A lameness examination in any horse is most easily and efficiently performed when the lameness is visible, and the endurance horse is no exception. It is usually not possible to make a specific diagnosis if a horse is not lame at the time of examination. Endurance horses are problematic because often a mild transient lameness that resulted in elimination from competition may not be visible the next day or even later the same day, although many horses have painful superficial digital flexor tendons (SDFTs) and SLs after a race. Low-grade, inconsistent, nonspecific lameness that cannot be localized is a frustratingly common scenario faced by veterinarians charged with keeping endurance horses sound. When possible, watching the horse trot while lame, application of hoof testers, noting the presence of any palpable abnormalities, and response to flexion or other manipulative tests help to narrow the possible causes. Diagnostic analgesia, adhering to the principle of starting at the bottom and working upward, is the standard most useful means of localizing the source of pain causing lameness when no palpable abnormalities are present. Sometimes, despite a careful and complete lameness examination, diagnostic analgesia, and ancillary diagnostic aids such as radiography, ultrasonography, scintigraphy, and even magnetic resonance imaging (MRI), a specific diagnosis cannot be reached. Some horses never “block out.” A careful neurological examination should then be performed because subtle neurological deficits may mimic or produce lameness. In other horses, pain causing lameness can be isolated to a specific region, but no lesion can be found. Like other athletic horses, endurance horses may have subtle gait abnormalities emanating from numerous areas, all contributing to suboptimal performance but difficult to identify individually. The advent of MRI has elucidated some previously elusive conditions of the distal aspect of the limb, especially in the proximal palmar metacarpal region and the foot.

Horses with pain causing lameness localized using diagnostic analgesia or clinical examination to a specific region in which there are no detectable radiological or ultrasonographic lesions should be reexamined by the most appropriate conventional imaging modality after 2 to 4 weeks or should undergo scintigraphic or MRI examination if warranted by the degree of lameness present. Stress fractures are particularly notorious for not being detectable on the first radiological examination and being readily apparent later. However, stress fractures are usually detectable using scintigraphy or MRI. If the lameness has resolved and no

lesion is detected on a recheck examination, it is reasonable to return the horse to light training. If lameness recurs, the lameness examination should be repeated.

Although “full-body” scintigraphy is ideally avoided, it is sometimes beneficial in horses that have an acute lameness that cannot be specifically localized. We have recognized the propensity for stress fractures to turn into catastrophic fractures; therefore obtaining a specific diagnosis is increasingly important. It should be borne in mind that the percentage of positive scintigraphic findings is higher for horses with acute, severe lameness than in those with chronic, low-grade lameness. Sometimes, despite every attempt at imaging and reimaging, the clinician is still left with a lame horse and no diagnosis. When this point is reached, a prolonged rest period (8 to 12 months) may be helpful.

COMMON CAUSES OF LAMENESS IN ENDURANCE HORSES

The principal cause of lameness is proximal palmar metacarpal pain,¹⁻⁴ but the other top 10 causes of lameness in endurance horses tend to vary somewhat in ranking from season to season. Although the problems listed here are the most frequently encountered, not only is the ranking variable, but also pathology in the proximal palmar metacarpal region and in the fetlock can be divided into subcategories that may overlap and are difficult to separate. The advent of the availability of sophisticated imaging techniques, especially MRI, has made it more difficult to write a list of the 10 most common causes of lameness in endurance horses because of the ability to recognize to a greater degree the interrelatedness of the anatomical structures involved. In addition, some injuries appear to be part of a spectrum or continuum that progresses through phases with time. Bearing this in mind, the following are the lameness problems seen most commonly:

1. Proximal palmar metacarpal pain
 - Proximal suspensory desmitis
 - Proximal palmar metacarpal stress pathology
 - Pathology associated with the second and fourth metacarpal bones
2. Foot problems
3. Metacarpophalangeal and metatarsophalangeal osteoarthritis, synovitis, and periarticular pathology
4. Stress-related injury of the distal aspect of the third metacarpal bone
5. Superficial digital flexor tendonitis
6. Myalgia of the paravertebral and gluteal muscles
7. Osteoarthritis of the centrodistal and tarsometatarsal joints
8. Desmitis of the suspensory ligament body and branches
9. Other bone injury
10. Exertional rhabdomyolysis

PROXIMAL PALMAR METACARPAL PAIN

The leading cause of chronic or recurrent lameness in endurance horses, regardless of terrain, is pain in the proximal palmar metacarpal region. Proximal suspensory desmitis (PSD) is often the primary problem. Pain associated with the lesions of the palmar aspect of the third metacarpal bone (McIII) or less commonly pain associated with the

second (McII) or the fourth (McIV) metacarpal bones, or the interosseous ligaments between the McII and McIII and the McIV and McIII may contribute to lameness. Injury to the proximal metatarsal region of the hindlimb also occurs but is less common.

Proximal Suspensory Desmitis

Desmitis of the SL typically develops in the later stages of a race when the horse becomes fatigued but may occur in the earlier stages of a race in an unfit horse or a horse that has had previous SL injury. It is also a common training injury. Lameness caused by PSD may be sudden in onset and severe or be more insidious in onset. Often, there is little or no detectable swelling, but careful palpation may elicit a painful response. However, many horses resent palpation of the proximal aspect of the SL and will give a false-positive response to even the most gentle and careful palpation. Horses with forelimb PSD are usually positive to distal limb flexion. Diagnostic analgesia is critical to definitively localize pain to the proximal palmar metacarpal region. The proximal palmar metacarpal region may be desensitized by (1) blocking the deep branch of the lateral palmar nerve laterally at the edge of the accessorimetacarpal ligament distal to the accessory carpal bone and the medial palmar nerve (high two-point or Wheat block, after Dr. John D. Wheat), (2) direct infiltration, (3) performing a high palmar and palmar metacarpal nerve block ("high four-point"), or (4) blocking the lateral palmar nerve in the longitudinal groove on the medial aspect of the accessory carpal bone.⁵ The first and last techniques have the advantage of avoiding inadvertent penetration of the distal palmar outpouchings of the carpometacarpal joint and the last technique avoids penetration of the carpal canal. Although lameness in endurance horses is seldom localized to the carpus, carpometacarpal joint pathology is increasingly recognized. When a high index of suspicion of proximal palmar metacarpal pain exists but the horse does not improve with one of the blocks, the block should be repeated, or one of the others should be tried because there may be some variability in response. Ultrasonographic examination of the SL is generally performed if diagnostic analgesia has localized the source of the pain causing lameness to this area. Ultrasonography is a less precise imaging modality than MRI, but it is more accessible and readily available to a general practitioner and remains a highly useful technique. PSD is characterized by loss of echogenicity of the dorsal-most fibers immediately distal to the carpometacarpal joint. Symmetry is important in determining whether acute SL injury has occurred, and the further distally the fiber loss extends (from zone 1 into zone 2), the worse the injury.⁶ Both forelimbs should be compared. Often, bilateral change is present, but the clinically affected side appears less echogenic (Figure 118-1). Examination of the limb in flexion with the digital flexor tendons and accessory ligament of the deep digital flexor tendon (DDFT) pushed aside can allow more complete evaluation of the medial and lateral lobes of the suspensory origin. If the pain causing lameness has been localized to the proximal palmar metacarpal region but the ultrasonographic appearance of the SL is within normal limits, there are several possible explanations: (1) inflammation of the ligament may exist without accompanying structural change; (2) abnormalities may be present in the ligament that are

Fig. 118-1 • Longitudinal ultrasonographic images of the palmar metacarpal soft tissues. The left forelimb is on the left. There is marked loss of echogenicity and disruption of the fiber pattern in the proximal aspect of the right suspensory ligament (arrows). Some loss of echogenicity is also seen in the proximal aspect of the nonlame left forelimb.

not detectable with ultrasonography⁷; and (3) there is pathology of other structures. It should be noted that most horses that have undergone any strenuous work will have some degree of ultrasonographic change (e.g., loss of echogenicity, fiber malalignment) in the proximal aspect of the SL⁶; the challenge is determining its clinical significance. Therefore combining the use of diagnostic analgesia and ultrasonographic comparison between limbs can be helpful in determining the relevance of a lesion. However, it is frustrating that there appears to be little correlation between ultrasonographic appearance of the SL, response to analgesia, ability to return to training, and incidence of recurrent lameness. MRI has revealed that this may be either because of SL damage that is present but undetectable using ultrasonography or injury of other structures.

Initial management of horses with PSD regardless of whether ultrasonographic changes are present is aimed at reducing inflammation. Combination therapy using systemic corticosteroids (a single injection of intramuscular [IM] triamcinolone acetate, 0.03 mg/kg), rest, a 7- to 14-day course of nonsteroidal antiinflammatory drugs (NSAIDs), and local therapy (e.g., ice, cold hydrotherapy, poulticing, and bandaging) is beneficial. Lameness in some horses with transient soreness and pain on palpation resolves without further problems. Infiltration along the axial borders of the McII and the McIV with corticosteroids is sometimes helpful to reduce acute proximal SL inflammation in the short term and may enable a horse to compete successfully if no structural abnormalities are present. The short-term benefit must be weighed against the risk of enabling the horse to compete and sustain further damage. It is critical to rule out stress fractures in the proximal aspect of the McII before infiltrating corticosteroids to minimize the risk of complete fracture. Correct foot balance is critical because a poorly balanced foot may contribute to SL strain. Weekly extracorporeal shock wave therapy (ESWT) for 3 to 5 weeks is used to reduce pain after the initial inflammatory period. Newer treatment modalities used with increasing frequency are intraligamentous injection of platelet-rich plasma, autologous stem cells derived from fat or bone marrow,

and matrix derived from the urinary bladder of pigs (ACell Vet, ACell, Inc., Columbia, Maryland, United States). Although healing time is not shortened, these treatments may increase the quality of healing and decrease reinjury rate.⁸ Surgical splitting of the proximal aspect of the SL and osteostixis of the proximal aspect of the McIII or the third metatarsal bone (MtIII) was described in three dressage horses in which conservative management had failed and in which there was enthesioid new bone on the McIII or the MtIII.⁹ This was reportedly successful. Fasciotomy is a technique used by some clinicians who treat other types of sports horses. I do not have enough experience with either technique to comment on their potential value in endurance horses. To accurately evaluate efficacy of various treatments, we must continue to define more precisely which structures have been injured. In general, I have had the most consistent success in endurance horses using initial antiinflammatory treatment, ESWT, rest, ensuring good foot balance, and a controlled rehabilitation and exercise program.

The horse should be restricted to handwalking until no lameness is apparent at a trot in hand on a hard surface without the benefit of systemic NSAIDs. The horse may then be gradually reintroduced to work if no structural abnormalities in the SL were identified. However, ultrasonographic examination should be repeated to confirm that no clinically significant structural change is present because the appearance of fiber damage observed ultrasonographically can lag behind the clinical perception of pain. Training may progress gradually if the lameness does not recur. If substantial structural change is present in the SL, if other ligamentous or osseous pathology has been identified, or if the lameness is persistent or recurrent, strenuous work should be avoided for at least 8 to 12 months. Although other sports horses may be able to return to training sooner, elite endurance horses are not able to quickly recover and require a considerably longer period. PSD is particularly treacherous to a horse's career because, initially, a horse often responds to a short period of rest, but the horse then becomes lame again when increased exercise is attempted. This scenario may happen repeatedly after short rest periods.

Much of the recommended rehabilitation program for horses with tendon or ligament injury depends on the horse's temperament and the amount of help and facilities available, but the best success is achieved with a controlled and gradual increase in exercise over 8 to 12 months. This may include turnout in a single-horse small paddock not much bigger than a stall; treadmill, handwalking, or walking machine exercise; and walking under tack. The bottom line has never changed: horses working in high-speed, strenuous athletic disciplines that sustain substantial damage to the SL (or SDFT) need 8 to 12 months of rest. The reason conventional wisdom becomes conventional is that it has withstood the test of time. Horses that sustain severe PSD may take 18 months to return to full training and will always be at increased risk of reinjury.

Stress Pathology of the Proximal Palmar Aspect of the Third Metacarpal Bone

Stress pathology of the proximal palmar aspect of the McIII includes avulsion and stress fractures, as well as more subtle bone and ligamentous change. Some avulsion fractures associated with the origin of the SL can be identified

Fig. 118-2 • Lateral bone phase scintigraphic images of the left and right forelimbs. There is intense focal increased radiopharmaceutical uptake (IRU) in the proximopalmar aspect of the right third metacarpal bone (McIII) (arrow) at the origin of the suspensory ligament. Note also IRU in the proximal aspect of the proximal phalanx of the left forelimb and IRU of the distal aspects of the McIII in both forelimbs.

using radiology or ultrasonography; others not identifiable using these imaging modalities are apparent using scintigraphy (Figure 118-2). MRI has enabled the recognition of fractures, prefracture pathology, and other changes occurring in the proximal palmar metacarpal and metatarsal regions unapparent using other imaging techniques. Avulsion fractures are part of an array of proximal palmar metacarpal pathology that includes palmar cortical and endosteal abnormalities, enthesophyte formation at the origin of the SL, severe palmar McIII so-called “bone bruising” characterized by increased signal intensity in fat-suppressed MR images, and stress fractures or linear defects within the cortex consistent with linear incomplete cortical fractures.^{3,7} Some proximal metacarpal fractures originate at the carpometacarpal joint surface; others originate from avulsion fractures that propagate distally.¹⁰ Incomplete fractures can be difficult to diagnose; one horse with bilateral proximal palmar McIII cortical fractures that extended into the diaphysis displayed a crouching stance, giving the appearance of a primary hindlimb lameness.¹⁰ The crouched stance in this horse and unusual gait occurs in horses with other bilateral forelimb fractures and is often confused with hindlimb pain (Editors). Horses with incomplete fractures should be box-rested for 30 to 60 days and confined alone in a small paddock or handwalked for an additional 60 days before resuming exercise. If unrecognized, there is a substantial risk that incomplete cortical fractures may propagate to become complete, with disastrous consequences (Figure 118-3).

Pathology Associated with the Second and Fourth Metacarpal Bones

Periostitis or exostosis of the McII and the McIV (splints) is much less common than other injuries in the proximal

Fig. 118-3 • Dorsopalmar radiographic image of the metacarpal region. Lateral is to the right. There is a wide intraarticular fracture of the proximal aspect of the third metacarpal bone, extending from the carpometacarpal joint distally and medially.

palmar metacarpal region and is included because of the close anatomical relationship to other structures in the region. It may be a minor problem necessitating a 2- to 4-week break from training, but abnormalities of the McII and the McIV may be associated with pathology of adjoining structures. Abnormalities identified with MRI include interosseous ligament pathology and reactive synostoses between the McII or the McIV and the McIII. This may be seen in association with injuries of the palmar cortex of the McIII and/or the SL, and the clinical significance of some of these findings is still undetermined. Loss of separation between either the McII or the McIV and the medial and lateral lobes of the SL with subsequent soft tissue apposition and adhesion formation may also occur and be of clinical significance. Radiological examination of an enlargement of the McII or the McIV should be performed to rule out a fracture. Ice, cold hydrotherapy, dimethyl sulfoxide (DMSO) gel, NSAIDs, and bandaging are used to reduce inflammation during the inflammatory period. Cryotherapy can also be used to reduce inflammation and will sometimes enable horses with reactive splint exostoses to continue in training and competition. Most uncomplicated splints resolve with time and treatment, although a nonpainful enlargement remains. If the exostosis continues to enlarge or if the area remains painful, training should be discontinued to avoid impingement on and damage to the SL. Sometimes SL damage occurs before recognition of the problem, and affected horses require a longer rest period. Fractures of the distal aspect of the McII or the McIV should be surgically removed, and horses should be given rest. Horses with splint exostoses that appear reactive or large enough to impinge on the SL may also be surgical candidates, although opinions differ. Horses undergoing distal splint ostectomy because of a fracture have a better prognosis than those receiving ostectomy because of

exostosis.¹ It may be that once SL damage has occurred, the window of opportunity for surgical intervention without adhesion formation is past. Any associated injury to the SL is the limiting factor in how quickly and how successfully horses with splint exostoses can be returned to work.

FOOT PROBLEMS

Problems with the feet are a frequent cause of elimination from endurance competitions, as well as being a common cause of chronic or recurrent pain. Foot problems occur in both forelimbs and hindlimbs but are more regularly seen in the forelimb. Many lameness eliminations related to the feet are transient in nature: bruising or a dislodged shoe. The importance of a properly trimmed, well-balanced, well-shod foot cannot be overemphasized, and a good farrier is an integral part of a successful endurance team. Because endurance horses train and compete over very long distances, foot balance has a huge impact on the support structures of the limb. Trimming and shoeing with a long toe and low heel can lead to direct heel trauma, as well as increased strain on the SL and digital flexor tendons. Good medial-to-lateral balance is vital to avoid problems with collateral ligaments of the distal limb joints and the collateral sesamoidean and distal sesamoidean impar ligaments. Farriers who are accustomed to working with horses that wear keg shoes may be impatient with the requirements of endurance horses, which can sometimes require a more innovative and time-consuming approach aimed at providing the foot with increased protection and support. Many, if not most, endurance horses are shod with full pads for the day of a race, which are later removed. Silicon gel is often used for this purpose.

Sole bruises occur frequently in horses traveling over hard ground. Horses show a bilateral lameness manifest as a shortened, choppy gait. Application of hoof testers around the solar margins of the foot elicits a painful response. Lameness is often more pronounced in one limb. Diagnostic analgesia of the foot in which the lameness is most noticeable may then result in contralateral limb lameness. Sole bruising may be accompanied by increased radiopharmaceutical uptake (IRU) in the distal phalanx and changes indicative of distal laminar and bone inflammation on MRI ("pedal osteitis").¹¹ Radiological abnormalities include loss of bone opacity at the margins of the distal phalanx and increased size and number of vascular channels, resulting in a ragged appearance. Lateromedial radiographic images may reveal modeling at the distal aspect of the distal phalanx, sometimes described as a "ski jump" appearance. Management is aimed at protecting the solar margins and reducing concussion. Wide-webbed, seated-out shoes, full pads, or rim pads can be used to accomplish these goals. Distal interphalangeal (DIP) joint synovitis may occur concurrently and is treated by intra-articular medication (hyaluronan and corticosteroid combinations). Sore feet often occur in conjunction with distal hock joint and back pain and may be the inciting cause. Each area must be addressed individually, as well as the horse as a whole, for treatment to be successful.

Palmar foot pain is less common in Arabian and Arabian crossbreeds than in larger breeds, but it does occur and can be an important cause of lameness. As more MRI examinations are performed, abnormalities in the navicular region

are identified with increasing frequency. Injuries identified in endurance horses with lameness abolished using palmar digital analgesia have included so-called "edema" of the navicular bone (i.e., increased signal intensity in the spongiosa in fat-suppressed images); distal border irregularities of the navicular bone; lesions of the DDFT from the level of the navicular bone to its insertion, with increased signal intensity in the palmar aspect of the navicular bone in fat-suppressed images; adhesions between the DDFT and the navicular bone; and disruption of the collateral sesamoid-equin ligament and its attachment to the dorsolateral aspects of the middle phalanx.

Endurance horses frequently exhibit inflammation of the coronary band ("coronitis") in the first 24 hours after competition. It may be focal (usually dorsal) or all the way around and is usually painful on palpation. Separation of the hoof wall from the coronary band may occur, and there may be oozing of serum from the coronary band. This is sometimes, but not always, accompanied by a bounding digital pulse. Interestingly, as alarming as this is, these horses do not usually progress to typical laminitis. The outer layer of hoof wall may peel away from the coronary band, but the horse is not lame, and there is no rotation or sinking of the distal phalanx. The episode is marked by bruising and a distinct defect in the hoof wall that usually grows out without further incident.^{1,3}

Endurance horses are also subject to laminitis that may be traumatic or metabolic in origin. Clinical signs become apparent 24 to 72 hours after competition. The severity may range from frightening, but mild, to disastrous. Horses without rotation or sinking are generally able to return to endurance competition. Horses with the worst outcomes often show few prodromal clinical signs. Proactive measures aimed at preventing laminitis should be considered in all high-risk horses after competition (those that are severely hemoconcentrated, exhausted, or have rhabdomyolysis, ileus, or diarrhea) because it is not possible to predict which horses will or will not have a satisfactory outcome. Continuously standing all four feet of the horse in an ice water slurry or water at 1° C up to the level of the carpus has proved to prevent onset of laminar damage^{12,13} but will not halt laminitis that is already occurring.¹³ Any horse that begins to shift weight or show any signs of discomfort after competition should certainly be treated, but by the time these signs are apparent, progression of the disease may be well underway. Flunixin meglumine (0.25 mg/kg intravenous [IV], thrice daily), phenylbutazone (2.2 to 4.4 mg/kg twice daily), acepromazine (0.025 mg/kg IM four times daily), pentoxifylline (7.5 mg/kg orally [PO] thrice daily) (Editors Note: Also see comments on page 373), and DMSO (1 g/kg IV diluted to 10% solution once or twice daily) are routinely used in various combinations, with the caveat that the horse should receive fluid therapy before administration of NSAIDs or acepromazine. Sole and frog pressure are also provided.

METACARPOPHALANGEAL AND METATARSOPHALANGEAL OSTEOARTHRITIS, CAPSULITIS, SYNOVITIS, AND PERIARTICULAR PATHOLOGY

Osteoarthritis (OA) of the metacarpophalangeal (MCP) and metatarsophalangeal (MTP) joints and periarticular

pathology is related to the ongoing nature of degenerative processes, chronic wear and tear associated with training and competing, and the fact that endurance horses may compete for several years. OA of the MCP or the MTP joints may occur with or without joint effusion and may be unilateral or bilateral, but is most often bilateral. OA is far more common in the MCP joints but also occurs in the hindlimbs. There is usually pain on flexion, and the joint often has a decreased range of motion and thickening of the joint capsule; acute or chronic synovitis may be present. Radiological changes may be subtle, such as narrowing of the joint space, or may consist of more obvious periarticular osteophyte or enthesophyte formation and joint modeling. Hypertrophy of the dorsal synovial pads with associated bone lysis at the proximal aspect of the sagittal ridge of the McIII is common, and osteochondral fractures may occur. Radiological changes do not always correlate with clinical significance; therefore diagnostic intraarticular or perineural (low palmar and palmar metacarpal) analgesia is used to confirm the site of pain. MRI findings may include effusion of the MCP joint with dorsal soft tissue accumulation and chronic, fibrotic synovial tissue and associated dorsal proximal plica formation. Lesions of the distal sesamoid ligaments may contribute to periarticular pain. Using MRI a diagnosis of medial oblique sesamoid desmitis is more common than lateral oblique desmitis. Acute, traumatic synovitis or capsulitis of the MCP joints may occur occasionally, but in general long-term management of chronic OA is the more common scenario, and management is similar to that in any other athletic horse. Local therapy (e.g., ice, cold hydrotherapy, poultice, and sweats), intramuscular glycosaminoglycans, intravenous hyaluronan, and judicious use of intraarticular hyaluronan and corticosteroids are beneficial. Repeated intraarticular corticosteroid injections may lead to a reduced response. Interleukin-1 receptor antagonist protein therapy may have long-term benefit, but most team and stable veterinarians preparing for a big race tend to continue to use intraarticular corticosteroid-hyaluronan combinations because the effects are more predictable. Withdrawal periods must be borne in mind. Horses with markedly hypertrophied dorsal synovial pads and osteochondral fragments usually require surgery.

STRESS PATHOLOGY OF THE DISTAL ASPECT OF THE THIRD METACARPAL OR THIRD METATARSAL BONE

Repetitive overloading injury of bone can lead to athletically induced fractures. Most fractures in endurance horses propagate from the MCP or the MTP joints, and lateral condylar fractures of the McIII are the most common type.¹⁴ This is consistent with reported common fracture locations in Thoroughbred racehorses.^{15,16} MRI has proved to be a valuable tool in early identification of stress pathology that is not visible radiologically. Identified abnormalities include asymmetry in trabecular architecture between the medial and lateral condyles of the McIII and the MtIII, and superficial palmar or plantar fissure lines at the articular surface. Alteration in structure of the articular surface and osteochondral and some subchondral irregularities associated with the medial and lateral condyles of the McIII and the MtIII are likely to be a reflection of traumatic

or degenerative cartilage and underlying bone damage, increasing potential for fracture at these sites.¹⁶⁻²¹ Bone trauma (so-called “bruising”) and, more commonly, chronic subchondral bone modeling of the distal aspect of the McIII or the MtIII of mature horses are recognized causes of pain, but may not increase risk of fracture formation.^{11,20,21} When pathological changes thought to increase the risk of fracture formation are identified, it is clearly prudent that the horse not continue training. However, it is not always clear what changes are pathological and increase fracture risk and what changes may reflect adaptive response to training. There is increasing evidence to support that many fractures in athletic horses occur not as isolated instances of a “bad step” but as a progression of pathological changes and stress remodeling over time, ultimately resulting in bone failure.¹⁵⁻¹⁹

Condylar fractures of the McIII or the MtIII may be complete or incomplete, displaced or nondisplaced, and may or may not be associated with joint effusion. Nondisplaced fractures are not always readily diagnosed but should be considered high on the list of differential diagnoses in an acutely lame endurance horse. The importance of careful physical examination and diagnostic imaging cannot be overemphasized because nondisplaced fractures risk becoming displaced if undiagnosed and sufficient confinement, support, and repair or stabilization are not provided. Many nondisplaced fractures are not diagnosed until several days after the occurrence of the injury and may require special imaging techniques. The presence of “moderate injury of the suspensory apparatus” increased the risk of condylar fracture in Thoroughbred racehorses.²² Given the high prevalence of PSD in endurance horses and the increasing numbers of condylar fractures identified, it is tempting to think that there may also be an association in endurance horses, and evaluation of risk factors for fracture in endurance horses is in progress.³

An unusual fracture type seen with increasing frequency in mature endurance horses is a transverse compression fracture of the distal metaphysis of the McIII at the residual physis (Figure 118-4). Horses with compression fractures of the distal aspect of the McIII have pain on palpation in the lateral condylar region and are usually suspected to have lateral condylar fractures, although no joint effusion is present. I have observed one horse with bilateral nondisplaced compression fractures, which had unilateral forelimb lameness. Horses with unilateral or bilateral nondisplaced fractures respond well to conservative management. One 7-year-old horse with no previous history of lameness pulled up grade 4 of 5 lame after a 40-km qualifying ride and had a transverse compression fracture with displacement of the distal epiphysis of the McIII.

Diagnosis in horses with bilateral fractures of the McIII or MtIII is challenging. Two horses with bilateral forelimb condylar fractures were reluctant to move and had a stance similar to horses with acute laminitis, rocked back onto the hindlimbs. Another horse with bilateral hindlimb lateral condylar fractures and a concurrent hindlimb sagittal fracture of the proximal phalanx appeared to have unilateral hindlimb lameness (on the side with the proximal phalangeal fracture) and was reluctant to move. On initial examination at the ride venue there was a palpable condylar fracture. After the limb with the obvious fracture was splinted and analgesics had been administered, the horse

Fig. 118-4 • Dorsopalmar radiographic image of a metacarpophalangeal joint, obtained with a horizontal x-ray beam so that the proximal sesamoid bones are superimposed over the epiphysis of the third metacarpal bone, distal to the physis. Lateral is to the right. There is a transverse compression fracture of the distal aspect of the third metacarpal bone at the residual physeal scar characterized by increased radiopacity of the physis (black arrows) and a small step incongruity laterally (white arrow).

walked reasonably comfortably. Subsequently swelling developed over the lateral condyle of the MtIII of the contralateral limb, and radiography revealed bilateral fractures, with a complete, displaced, comminuted lateral condylar fracture in the less lame contralateral limb.¹⁰ It must be recognized that bilateral fractures do occur but may not be obvious. However, if a horse has an unusual stance or is reluctant or unable to move, radiographs of both limbs should be obtained to rule out fractures of the proximal phalanx and the distal and proximal aspects of the McIII or the MtIII. It should be standard practice to obtain radiographs of the contralateral limb before placing a horse under general anesthesia for surgery.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Superficial digital flexor (SDF) tendonitis may be acute or chronic, low grade or severe. Acute ruptures or partial ruptures occur occasionally during competition. Although more common in forelimbs, SDFT injury also occurs in hindlimbs. Initial management is directed at trying to reduce swelling and inflammation and to relieve pain. Ice, bandaging, and NSAIDs are used to this effect. Dehydrated horses should not be treated with NSAIDs until they are rehydrated. Horses that sustain a rupture or partial rupture of the SDFT have a poor prognosis for return to endurance competition.

Horses with less severe damage to the SDFT can be more challenging to diagnose and manage. Training injuries, wherein the SDFT may be warm and tender on palpation, occur relatively frequently. Lameness is often not apparent. The initial unremarkable ultrasonographic appearance may belie underlying structural damage, which is not yet visible. A second examination should be performed 7 to 10 days later because the ultrasonographic appearance is often worse at that time than it is initially. Horses with transient heat and tenderness but no swelling or fiber damage can usually be safely returned to training within 2 to 4 weeks.

after the resolution of clinical signs. If the tendon is enlarged or if fiber separation has occurred, a substantially longer absence from training and competition is required.

Endurance horses that sustain tendon injuries in training or competition are managed similarly to any athletic horse. A one-time dose of intramuscular triamcinolone acetonide (0.03 mg/kg), local application of ice for the first few days, cold hydrotherapy, bandaging, poulticing, and NSAIDs for 2 to 3 weeks are beneficial in reducing initial inflammation. Surgical splitting of those tendons with central core lesions, autogenous liquid bone marrow injection of split SDFTs, and intralesional stem cell, platelet-rich plasma, or ACell injection may be beneficial, but whether these therapies are more beneficial than rest alone is uncertain. Endurance horses with SDF tendonitis have traditionally had a better prognosis for return to competition than horses that race over short distances at higher speeds. Prognosis may be less encouraging in the future as speeds of endurance competitions increase.

PARAVERTEBRAL AND GLUTEAL MYALGIA

Paravertebral myalgia is related to repetitive stress over long distances and is exacerbated by a fatigued, unbalanced rider. Unbalanced movement of the horse contributes to muscle fatigue and often occurs as a result of the horse altering his gait to protect weaknesses. Unfortunately, concomitant diminished rider capability occurs in horses experiencing muscle fatigue. Horses ridden by fit, experienced riders are less subject to battering of the paravertebral muscles than those ridden by novices or poorly balanced riders. FEI rides require that a minimum weight of 75 kg be carried. A fit, competent rider is able to adjust his or her weight distribution to help a tiring horse, but a horse ridden by a less capable rider may be better off with the dead weight of a lead pad.

A horse that has strained or injured the paravertebral muscles appears stiff or rigid rather than lame, and instead of flexing and extending the spine normally when palpated, the horse tends to stiffen, squat, or crouch. It may be difficult or impossible to differentiate muscle pain from pain emanating from vertebral articular facets or dorsal spinous processes. Paravertebral myalgia can occur from a gait change induced by sore feet or sore hocks. Treatment consists of removing the inciting cause when possible and reducing inflammation. Most horses respond to 2 weeks of reduced exercise in conjunction with NSAIDs and pulsed muscle massage. Injection of the paravertebral muscles with an antiinflammatory agent can also be beneficial. The longissimus dorsi muscles are injected bilaterally, approximately 3 cm lateral to the dorsal midline, at five to six sites approximately 5 cm apart using a 22-gauge 1.5-inch needle, from the midthoracic area moving caudally, with 2 mL/injection site of an aqueous solution of soluble salts of the volatile bases from Sarraceniaceae (Sarapin, High Chemical Company, Levittown, Pennsylvania, United States) alone or mixed equally with estrone sulfate (50 mg).

Inflammation of the gluteal muscles also occurs with relative frequency in horses subjected to strenuous work over long distances. The horse exhibits stiffening and shortening of stride; pressure on the superficial and middle gluteal muscles produces a painful response; and the horse may crouch down or move away during palpation.

Swelling or asymmetry may be apparent in the acute stages, with elevation of serum muscle enzyme concentrations. Severe inflammation of the gluteal muscles and accompanying rhabdomyolysis are serious problems that are discussed in the metabolic abnormalities section (see page 1147). NSAIDs must never be administered to a horse with acute gluteal muscle inflammation unless it can be ascertained that hydration and renal function are not compromised. Endurance horses with mild gluteal muscle inflammation usually respond to NSAID therapy, pulsed muscle massage to alleviate muscle pain and spasm, and a short (2 to 3 weeks) rest period. Gluteal soreness may occur in conjunction with forelimb lameness because horses may alter the hindlimb gait to avoid interference. The primary lameness must be managed to hasten resolution of gluteal muscle inflammation.

OSTEOARTHRITIS OF THE DISTAL HOCK JOINTS

OA of the distal tarsal joints usually affects both the tarso-metatarsal (TMT) and centrodistal joints and is often bilateral, with one limb usually more affected than the other. Joint effusion is not palpable, but occasionally during joint injection of the TMT joints one gets the impression that there is increased pressure and volume of synovial fluid. Affected horses are positive to hindlimb flexion and show variable sensitivity to the Churchill test. Radiological abnormalities include joint space narrowing and osteophyte formation but do not always correlate with clinical signs. If the clinical picture is one of distal hock joint pain, intraarticular medication is usually administered; a positive response is empirical evidence of a correct diagnosis. This approach obviates the need to go back after a positive response to intraarticular anesthesia to administer intraarticular medication. Distal hock joint pain frequently occurs concurrently with paravertebral muscle pain and sore front feet: the "terrible triad." This is likely to be a result of a horse with sore front feet altering his gait in such a way as to cause strain in the paravertebral muscles and hocks. The best results are obtained when all three problems are treated simultaneously; otherwise, the pain in one area and gait alteration and soreness in another become a never-ending and ever-enlarging cycle.

If pain is localized to the tarsus but radiological findings are negative, consideration should be given to the possibility of less common causes. I have evaluated two endurance horses with nondisplaced parasagittal fractures of the talus. Pain was localized to the tarsocrural joint using diagnostic analgesia. In both horses there was IRU, and a clear fracture line was visible with MRI (Figure 118-5). MRI examination has been useful to diagnose incomplete fracture of the third tarsal bone and evidence of bone repetitive overloading injury in the talus, central, and third tarsal bones. Curb, inflammation of the long plantar ligament, or SDFT distal to the calcaneus may also be a cause of pain in the tarsal area but is usually identified by local pain and swelling.

DESMITIS OF THE SUSPENSORY BODY AND BRANCHES

Desmitis of the suspensory body and branches is more obvious than PSD because there is usually palpable swelling. It most frequently occurs as acute, often severe, traumatic

Fig. 118-5 • Transverse magnetic resonance image of a hock at the level of the talus. There is linear increased signal intensity from dorsal to plantar consistent with a sagittal fracture (arrows) of the talus.

injury during training or competition. Low-grade, chronic desmitis often precedes acute onset of lameness. Ultrasonographic examination of the SL body and branches is easier to interpret than ultrasonography of the proximal aspect of the SL. Initial and long-term management is essentially the same as for horses with PSD. Suspensory desmitis often occurs in conjunction with pathology of the fetlock joint, which must be managed simultaneously.

OTHER BONE INJURY

It is clear that most common fractures result from accumulated microdamage,¹⁵⁻²⁰ but inconsistent, unpredictable surfaces may cause increased and uneven loads on the structural integrity of bone.²³ Horses that get loose or run off over uneven ground or variable surfaces (sand to tarmac) may sustain unusual fractures. The presence of preexisting stress pathology increases this risk. Veterinarians working at endurance rides should be prepared to deal with emergency fracture management. A Kimzey splint over a suitable bandage is the most convenient and effective means of stabilizing a lower limb fracture or disruption of the suspensory apparatus. "Ski-boot" splints are equally effective but are more difficult to fit and apply correctly. Additional splint materials for stabilization of upper limb fractures, such as polyvinylchloride pipe cut into circumferential thirds and to appropriate lengths or a Kimzey splint with a proximal extension, should also be available.

While fractures of the distal aspect of the McIII or the MtIII are most common, the second most common fracture in endurance horses involves the proximal phalanx, and, importantly, horses often have acute lameness with limb instability from displaced fractures.¹⁴ Sagittal fractures are the most common followed by those that are comminuted. Proximal phalangeal fractures also occur in the dorsal plane and the dorsal and sagittal planes combined. Numerous radiographic views are essential to elucidate fracture configuration.

Less common fractures include radial, humeral, and scapular stress fractures diagnosed scintigraphically. A horse with a complete humeral fracture had no initial swelling or crepitus, but the limb could be abducted to an abnormal degree, and the presence of a fracture was confirmed radiologically. Other less common fractures of the distal phalanx (type V), proximal sesamoid bone (apical), middle phalanx (abaxial palmar eminence fracture), third trochanter of the femur, and pelvis (ilium and ischium) are occasionally seen.

EXERTIONAL MYOPATHY

Exertional myopathy, rhabdomyolysis, or myositis in endurance horses is not so much a lameness problem, but it is part of a larger picture of fatigue and metabolic abnormalities. It manifests as stiffening and shortening of the stride in all four limbs and may be accompanied by trembling and profuse sweating. It usually occurs either in the very early or very late stages of a ride. Severely affected horses often have pronounced swelling, hardening, or asymmetry of the gluteal muscles. Fluid therapy (0.9% sodium chloride) is the mainstay of treatment, and horses with severe myopathy may require large volumes (40 to 80 L) of fluids. Horses with myoglobinuria ideally should urinate normal-colored urine before administration of flunixin meglumine (0.55 to 1.1 mg/kg or 250 to 500 mg/450-kg horse). When in doubt as to the status of renal function, it is better to give the lower dose and repeat if necessary. Blood urea nitrogen and creatinine concentrations should be monitored, if possible. Portable, relatively inexpensive, user-friendly blood analyzers now make it possible to monitor renal function indicators and muscle enzymes, as well as electrolytes and packed cell volume. Methocarbamol (5 to 25 mg/kg IV) is helpful in many horses. DMSO (1 g/kg IV in a 10% to 20% solution) may also be beneficial. Dantrolene is not generally used because it is not available in an intravenous form, is expensive and not well absorbed when administered orally at recommended dosages, and is ideally given before exercise to be most effective. Horses that have suffered a clinical episode of exertional myopathy or myositis should not be returned to training until muscle enzyme concentrations return to normal values, bearing in mind that what is normal for a particular endurance horse may be higher than published ranges for other types of horses. Some endurance horses in regular training that show no clinical signs of myositis may have resting aspartate transaminase (AST) and creatine kinase (CK) values that commonly reach the range of 1000 U/L to 40,000 U/L or higher after a race or long training ride.³ Resting CK and AST values, as well as those after races or long rides, for individual horses must be known to determine whether elevated muscle enzyme concentrations are a result of new muscle damage causing lameness or the reason for subclinical poor performance.

METABOLIC PROBLEMS

Avoidance, diagnosis, and management of metabolic problems are some of the many controversial topics currently faced by the sport of endurance. Veterinarians experienced in the sport of endurance racing believe that fatigued, metabolically compromised horses are at increased risk of developing musculoskeletal injury. The highly competitive

nature of the sport has led to a large number of horses with metabolic abnormalities. Although veterinarians are now more adept at recognizing subtle signs of exhaustion and often treat horses proactively, a substantial number of horses still have serious problems. The “exhausted horse syndrome” described many years ago²⁴ is still very much in evidence today. Exhausted horses undergo massive but poorly understood fluid and electrolyte shifts that lead to multiple organ system compromise. Initially, there is persistent elevation of the heart rate, a prolonged capillary refill time, and profound ileus that do not respond as anticipated to fluid therapy, electrolyte supplementation, or analgesics. Synchronous diaphragmatic flutter may be present. Horses with ileus and signs of abdominal pain should be checked for the presence of gastric distention by passing a nasogastric tube. Small intestinal volvulus after endurance competition is a recognized phenomenon,^{2,25} and horses with gastric reflux that do not respond to analgesics should be referred. A number of horses with small intestinal volvulus have experienced intractable pain and required intravenous general anesthesia for transport. Although dangerous, use of this technique has resulted in successful outcomes in horses that otherwise would not have survived.² Two horses transported under intravenous general anesthesia that subsequently underwent small intestinal resection and anastomosis successfully returned to race the following season.

It cannot be overemphasized that exhausted, hypovolemic, or dehydrated horses or those with severe myositis must not be treated with NSAIDs until they are adequately reperfused. To do so risks renal failure, and these horses are already at high risk for renal failure as a result of hemodynamically mediated vasoconstriction. Vasoconstriction may contribute to subsequent renal ischemia that is exacerbated by NSAID-mediated inhibition of prostaglandin synthesis. If severe lameness or myositis is present, many veterinarians are lured into treating immediately with phenylbutazone or flunixin meglumine. This temptation must be resisted. Lameness, even those with fractures and without overt evidence of metabolic compromise, should receive fluid therapy before NSAID administration. Horses with acute tendon or ligament injuries should have the affected limb placed in ice, and those with fractures should have appropriate external coaptation applied. Endurance horses should receive at least 10 L, and preferably 15 to 20 L, of intravenous 0.9% sodium chloride (or other available isotonic fluid) to restore renal perfusion before NSAID administration. This volume represents approximately half of the required fluid replacement volume for a moderately hypovolemic horse. Treatment of moderate hypovolemia, the decrease in circulating plasma volume responsible for clinical signs of tachycardia and prolonged capillary refill time, and dehydration (excessive loss of water from the body tissues) generally requires a *minimum* of 50 mL/kg of crystalloid fluids to replace deficits (20 L in a 400-kg horse). Horses with severe hypovolemia require large-volume replacement (60 to 90 mL/kg). The endpoint for fluid therapy is based on the response to treatment, which is closely monitored.

High-volume fluid replacement is by far the most effective treatment for horses suffering from severe hypovolemia that have collapsed or are on the verge of collapse. Two intravenous catheters should be placed; 14- or 12-gauge

catheters are adequate if fluids can be delivered under pressure, and 10-gauge catheters are more difficult to place and usually require a cutdown. It is important that catheters are 140 mm (5.5 inches) long and are sutured in place to prevent dislodgement and extravasation of fluid. Aseptic technique is imperative to avoid the unwelcome complication of infectious thrombophlebitis. Horses with profound hypoglycemia may collapse, be reluctant to move, or exhibit a “sawhorse” stance and respond well to administration of 50 to 100 mL of 50% dextrose diluted in 3- or 5-L bags of saline, repeated as needed. Prednisolone sodium succinate (2.2 mg/kg IV or 1 g/450-kg horse; Solu-Delta-Cortef, Pfizer Inc., New York, New York, United States) can be helpful in stabilizing horses that have collapsed or are showing neurological signs, but it should be borne in mind that exhausted, hypovolemic, or dehydrated horses are also at risk for subsequent pleuropneumonia and laminitis, and large doses of corticosteroids may increase this risk. Profound leukopenia may precede the onset of pleuropneumonia, and appropriate antibiotic therapy should be instituted in leukopenic horses. It is wise to recheck the white blood cell count and creatinine levels of distressed horses the day after the race, even if they have been previously treated because endurance horses may be immunosuppressed or azotemic following competition. Laminitis may strike several days following postrace exhaustion. Prophylaxis for laminitis should be instituted in horses that are depressed, inappetent, leukopenic, or febrile.

Synchronous Diaphragmatic Flutter

Synchronous diaphragmatic flutter, or “thumps,” a condition in which the phrenic nerve is stimulated by atrial depolarization, causing contraction of the diaphragm and consequent “thumping” of the flank in time with the heartbeat, has traditionally been considered a sign of serious electrolyte imbalance, most commonly hypocalcemic, hypochloremic metabolic alkalosis.²⁵ In my experience, blood levels of total or ionized calcium are often normal, and the presence and degree of alkalosis are variable. Measured electrolyte values may not reflect total body stores, and there is no convenient way to simultaneously measure chloride and ionized calcium. Many horses with thumps have no other identifiable abnormalities, and rest, food, and water may be all the treatment required. Before 2009, FEI rules dictated that horses be eliminated for thumps, but now disqualification is left to the discretion of the Commission Veterinarians. Most Commission Veterinarians require that horses with thumps be reexamined; if the condition is still present after the horse has been rested, fed, and watered, the horse is usually eliminated. Unfortunately, most horses with thumps take longer to resolve the condition than the limited time period given in which to represent, even if other metabolic abnormalities are not present. Horses eliminated from competition may be completely normal, and Commission Veterinarians may be in a bit of a conundrum: they do not wish to send a potentially compromised horse back out onto the course, nor do they wish to eliminate a competitor that is capable of safely completing. One must not lose sight of the forest for the trees, and it is essential to look at the overall picture.

Horses with thumps accompanied by serious metabolic abnormalities usually respond to intravenous calcium

supplementation (100 to 300 mL of 20% to 23% calcium borogluconate diluted in 3 or 5 L of saline given over 15 to 20 minutes, to effect). It has been proposed that horses prone to thumps be fed a low-calcium diet before competition to enable more efficient mobilization of calcium from bone reserves during periods of stress.²⁶ Although making physiological sense, this strategy has not been successful. Unfortunately, some horses appear to have a low threshold for development of thumps and are likely unsuitable for endurance use.

Prevention of Metabolic Problems

Many, if not most, metabolic problems could be avoided by the use of common sense, but in the heat of competition common sense is one of the first things lost. Although both horse and rider get tired, an astute rider is able to determine when the horse has had enough. The horse should be stopped if it is not eating and drinking at rest stops, is reluctant to move forward, or is stumbling.

Misuse of electrolyte replacement preparations is common, and concentrated electrolyte preparations that are force-fed may be detrimental if the horse does not

drink. They increase the tonicity of the gastrointestinal lumen, cause fluid influx, and contribute to dehydration. Poorly formulated electrolyte preparations full of sugar cause hyperglycemia and a subsequent insulin-mediated hypoglycemic crash. Hay fed to a well-hydrated horse acts like a sponge, or water reservoir, in the large intestine. Whereas in flat racehorses hay and water are often withheld before racing, endurance horses should be encouraged to eat hay and should have free access to water before competition so that they will have a fluid reserve available for absorption from the large intestine.

Now one compulsory recheck examination is required at one or more Vet Gates at all FEI rides. This recheck examination has been exceedingly useful in identifying horses that pass the initial veterinary examination but then deteriorate during the mandatory hold period. Without a "second look," horses may return to the course and further worsen. Focusing on the overall safety of the horse by early identification of metabolic and lameness problems is paramount and is in the best interests of the horse. It is incumbent on those of us entrusted with the stewardship of these horses to ensure that we do our utmost to manage them wisely.

Chapter 119

Lameness in the Polo Pony

*Paul Wollenman, P. J. McMahon,
Simon Knapp, and Mike W. Ross*

HISTORY OF THE SPORT

Polo was the first equestrian sport in recorded history. With strong ties to military traditions, the game originated in China in AD 272 and was often substituted for war games in preparation for military battle. Polo evolved into an organized sport and spread into Greece, India, and China, where the British colonies adopted the game. During the nineteenth century, the game became more refined in Great Britain and eventually found its way into the northeastern United States in 1876. Today polo continues to be one of the fastest and most dangerous equine sports in the world. Polo is no longer a sport only for the wealthy; an increasing number of small clubs start up each year that attract people of moderate incomes to take lessons, buy horses, and begin to play. The sport has become more complex, with international professional players competing year-round on different teams. Thus professional polo coaches, umpires, trainers, and breeders have emerged, solidifying polo as a genuine equine sport industry. Playing seasons in the northern and southern hemispheres are followed by nomadic players, grooms, horses, and spectators. During the winter months in the United States, thousands

of horses enter Florida and California, where the tropical climate is conducive to world-class polo tournaments. During the spring, summer, and fall seasons these horses travel across the Midwest, up the northeast coast and into Canada. The high-goal season begins in the summer in England and Spain, but in the southern hemisphere, the season in Argentina commences in the fall.

POLO AS AN INDUSTRY

Today three types of polo are played: outdoor, indoor (arena), and snow polo. Outdoor polo is by far the most popular and is played on a large, finely manicured grass field measuring 274 m (300 yards) by 137 m (150 yards) (Figure 119-1). Injuries are related to fatigue (because of the distances covered), stopping, turning, speed, and surface consistency, depending whether the soil beneath the grass is compact or soft. Arena polo is played in much smaller arenas and is more common in collegiate settings. Injuries tend to be less frequent and are usually impact related. Snow polo is regarded as a novel exhibition sport played on the surface of a frozen lake and produces surprisingly few injuries. Obviously, footing and surface conditions often can be responsible for the type of lameness seen. Heavy, soft, grass polo fields and deep, sandy, uneven exercise tracks are frequently responsible for proximal suspensory desmitis (PSD), suspensory branch desmitis, and metacarpophalangeal joint sprains. Hard fields, exercise tracks, and polo field sideboards may cause hoof and pastern region injuries, and hard, fast ground predisposes horses to superficial digital flexor (SDF) tendonitis.

In outdoor polo each team is composed of four players, and each member brings an average of seven to eight horses to the field. A game normally runs for six chukkers (a chukker is 7 minutes), and a different horse is used for

Fig. 119-1 • Outdoor polo is the most popular format for the game today. Close proximity of horses and riders explains why polo ponies often develop injuries related to direct trauma. Polo is only played right-handed.

each chukker. In higher goal polo, numerous mounts are used in single chukkers. Therefore in a single match there may be 50 to 55 horses playing over 1.5 hours. The number of horses that are required to mount a polo team makes each owner's total investment much larger than that for other equine disciplines.

Polo requires the speed and stamina of a Thoroughbred (TB) or a TB-cross horse, the ability to stop and turn quickly, and the boldness to meet and collide with other horses at high speed. Although called ponies, polo horses stand 15 to 16 hands tall, and mares are preferred to geldings at a ratio of 10:1. Most trainers look for a fine neck and throat-latch, a good strong shoulder, powerful hip, quiet disposition, and a responsive, light mouth. Many horses have not raced, so few racetrack-related injuries are found in polo ponies. Argentina, New Zealand, and Australia are the only countries that specifically breed large numbers of horses for polo competition. Horses indigenous to these countries tend to have more bone than those in the United States and Europe, rendering them slightly more durable. Argentina has historically produced the most horses used solely for polo. Since 1970, thousands of Argentine horses have been imported into the United States and Europe, primarily because such a large selection was available at low cost. During the 1970s, inexpensive American former racehorses were sold as polo prospects, but many had numerous orthopedic problems. Today the price of high-goal Argentinian polo ponies continues to increase, and as the cost of importing horses into the United States increases,

Fig. 119-2 • Daily legging up is an important part of training polo ponies. Ponies often are tied together in sets of four to five, and although this practice saves time, horses in close contact are at risk of traumatic injury.

economic demands necessitate a greater influx of American TBs into polo. Recently, embryo transfer has been used by players from the United States. Embryos are collected from top playing mares during the off-season and from retired superior mares to produce numerous foals each year. Argentina and, to a lesser extent, Australia have led the movement toward embryo transfer.

Most horses are 3 to 4 years old when introduced to the game, and 2 years of training and playing generally are required before a pony becomes seasoned. Exceptionally talented horses are playing high-goal polo at 6 years of age. By the age of 12 to 14 years, speed usually has begun to diminish, and horses are sold to less demanding players. By the age of 15 to 16 years, depending on temperament, polo ponies may be sold to beginners before being retired.

Neck reining is paramount in training a polo prospect because the rider uses only one hand for control. Wide range of movement, the ability to stop and turn quickly, and the ability to exhibit rapid bursts of speed are required. How well and smoothly the horse performs these maneuvers often determines the number of years the horse stays sound and competes successfully. In addition to schooling, fitness training consists of daily galloping (legging up). Ponies often are tied together in sets of four to five. This time-saving practice teaches the horses to travel more calmly together in close contact but can result in traumatic injuries to the lower limbs (Figure 119-2).

Polo ponies are shod with special rim shoes in front that allow for traction and pivoting without applying excessive torque to the lower limb. Medial and lateral heel calks on the hind shoes are helpful for stopping abruptly but often result in coronary band and pastern region lacerations to other horses during competition. For safety reasons, the Great Britain Polo Association only permits a lateral calk on each hind shoe, whereas the United States Polo Association allows medial and lateral heel calks. The size limit for calks is regulated but seldom enforced.

Therapeutic corrective shoeing is problematic in playing horses (those actively being used in polo competition) because they may lose traction and maneuverability. Some common shoeing modifications include squared, rolled, and rocker toes; elevated and full-shod heels; and padded soles. The standard support and protection afforded the horse during exercise are leg wraps and coronet boots. All legs are wrapped with double-layer rolled cotton bandages. Impact-resistant European racing boots may be added to cover the metacarpal regions to protect against mallet and hoof trauma. More recently, especially on previously injured limbs, cotton leg bandages have been replaced with neoprene fabric wraps that extend below the fetlock joint and provide additional support. Despite these additional protective barriers, horses may still injure tendons and receive skin lacerations during a game or practice.

Drug testing of polo ponies is not yet compulsory in the United States, and no mention of prohibitive medication is addressed in the United States Polo Association rulebook; however, limited testing is done in Great Britain and France. Attending veterinarians often work for many competing teams within the same tournament, and prompt assessment of injuries is important. Low doses of nonsteroidal antiinflammatory drugs (NSAIDs) are commonly used, especially in horses with wounds and solar bruising. The general aim is to have as many sound horses as possible sharing the workload during a match to avoid the practice of double-chukker (using the same horse for two chukkers).

Minor conformation abnormalities in polo ponies often can be overlooked, but some faults predispose ponies to specific injuries. Long toes and underrun heels may result in tendonitis of the deep digital flexor tendon (DDFT) and palmar foot pain. Toed-in horses are prone to develop lateral suspensory branch desmitis, whereas toed-out horses are more likely to injure the medial branch. Horses with long pasterns and long third metacarpal bones (McIII) are at increased risk of tendonitis of the superficial digital flexor tendon (SDFT).

The most common sources of lameness in polo ponies are similar to those seen in most other equine sports. Polo ponies are at higher risk for traumatic injury because of the high-impact play and the practice of tethering of horses in close proximity to other horses during shipping, exercise, and polo tournaments. Causes of lameness often seen concurrently include palmar foot pain and PSD and osteoarthritis (OA) of the fetlock joint with chronic suspensory branch desmitis.

LAMENESS EXAMINATION

Horses should be stabled overnight so that they cannot warm out of subtle lameness. The horse is first examined in the stall and then as it walks from the stall. The horse is observed at a trot in a straight line on a hard surface and is circled in both directions. Most polo ponies are reluctant to lunge. If necessary, the horse may be observed under saddle, but Argentine ponies generally resist trotting when ridden.

A systematic examination at rest is begun with the hoof and hoof tester evaluation and then continued proximally in the limb, noting evidence of pain, swelling, or

obvious injury. Findings always should be compared with the contralateral limb, especially when palpating the body of the suspensory ligament (SL). Joints are assessed for range of motion and a painful response to flexion. Lower limb flexion is followed by carpal or upper hindlimb flexion. Walking the horse briefly between flexion tests to allow an aggravated response to wear off is wise.

One of us (PJM) attends to many older polo ponies that have effusion of the metacarpophalangeal joints, manifest a positive response to flexion, and even may have visible and radiological evidence of OA, but lameness often is abolished using low palmar digital analgesia. Palpation may reveal one or more fractured splint bones with callus, but the rest of the limb should be examined because the cause of lameness may be elsewhere.

If a definitive diagnosis cannot be made, diagnostic analgesia is performed. Because drug tests are not performed, local anesthetic solutions can be used for diagnostic purposes in actively competing horses. When performing a nerve block, it is important to remember that the block may affect a larger area than intended, primarily related to diffusion of local anesthetic solution to surrounding tissue. High palmar analgesia can mask middle carpal joint pain, and palmar nerve blocks performed at the base of the proximal sesamoid bones (PSBs) can eliminate pain associated with the fetlock joint. For this reason, the horse should be observed at the trot shortly after injection of local anesthetic solution and then again after an appropriate wait.

To reduce time and money spent on lameness diagnosis, one author (PW) prefers to block large areas during the initial examination. Specific blocks then are performed, if necessary, the following day. For example, a horse that shows neither a sensitivity to hoof tester examination nor an increased digital pulse amplitude may go sound after palmar nerve blocks performed at the base of the PSBs. The following day the same horse may show slight improvement after palmar digital analgesia and a 100% improvement with intraarticular analgesia of the distal interphalangeal (DIP) joint. However, two authors (PJM and MWR) prefer to start distally and work proximally in a systematic fashion.

Intraarticular analgesia is used extensively in polo ponies because it is more specific than perineural analgesia. Although intraarticular analgesia requires aseptic preparation and carries a small risk of infection, clients are generally receptive. If lameness is localized to a specific joint on clinical examination, therapeutic agents such as corticosteroids and hyaluronan can be added to local anesthetic solution to confirm diagnosis and initiate treatment simultaneously. One author (PW) uses combination diagnostic and therapeutic arthrocentesis typically in the DIP and proximal interphalangeal (PIP) joints. The horse's immediate response to local analgesia is noted, and response to therapy is usually evident 2 to 3 days later. Another author (PJM) frequently uses combination diagnostic and therapeutic injections in the DIP and distal hock joints. Combination injections can also be used simultaneously to diagnose and treat back pain. The dorsal aspect of the dorsal spinous process and the interspinous space can be infiltrated with a combination of local anesthetic solution, Sarapin (High Chemical Company, Levittown, Pennsylvania, United States), and a corticosteroid. Response to infiltration is evaluated immediately by

riding the horse after injection, and response to medication is evaluated over the next several days.

Because metacarpophalangeal joint disease and splint bone injury are common sources of pain in the polo pony, one author (PJM) prefers specifically to differentiate these sources of pain by first performing intraarticular analgesia of the metacarpophalangeal joint and then later performing a low palmar block. If low palmar analgesia is performed first, both potential sources of pain are eliminated. If pain is detected on palpation of bony exostoses of the splint bones, these areas can be blocked first, before a systematic blocking strategy is followed. One author (PJM) refers to this as the splint block. This block is performed by first blocking the palmar metacarpal nerve distal to the exostoses. If improvement is not seen, the palmar metacarpal nerve just proximal to the exostoses is then blocked (2 mL of local anesthetic solution). A biaxial splint block can be performed if exostoses are found medially and laterally. This block should be done well below the origin of the SL to clearly differentiate PSD from splint bone disease. Splint disease, mainly from direct trauma from mallets and calk trauma, is common in hindlimbs. Diagnostic analgesia is performed as described in the forelimb.

Hindlimb PSD has become a common diagnosis because we are now more aware of it. In the United Kingdom, a variation of the high plantar nerve block, analgesia of the deep branch of the lateral plantar nerve (see Chapter 10), is commonly used to diagnose PSD. Three milliliters of local anesthetic solution is injected deep to the proximal aspect of the lateral splint bone, and 2 mL each is placed over the medial and lateral plantar nerves. If this block is unsuccessful in abolishing pain, each hock joint compartment is blocked subsequently. This procedure then is followed by fibular and tibial nerve blocks. In Argentina, chemical neurolysis (long-term nerve block) of the fibular and tibial nerves frequently is performed for horses with distal hock joint pain or PSD (PJM).

UNDIAGNOSED LAMENESS

In some horses the lameness is inconsistent and/or subtle, and diagnostic analgesia cannot be performed. Nerve trauma on the abaxial aspect of a PSB may cause episodic, transient severe lameness. An option in a horse with mild inconsistent lameness is to treat with phenylbutazone (2 g orally [PO] twice daily) for 5 days and then reassess the horse. If lameness resolves and does not return after treatment is discontinued, the horse gradually is put back into work. In horses with inconsistent lameness that fail to respond to rest or therapy, we recommend nuclear scintigraphic examination. Exercise intensity can be increased in horses with subtle lameness but is done so with caution. Lameness may become more apparent to the point at which diagnostic analgesia can then be performed. In a horse with recurrent episodes of hindlimb lameness, the veterinarian should be aware of the possibility of an ilial stress fracture (SK).

Occasionally, a polo pony becomes acutely non-weight bearing, with lameness lasting only a few minutes and resolving before examination is possible. If this sort of episode becomes recurrent in the same limb and physical examination reveals no clinically significant findings, we refer the pony for nuclear scintigraphic examination.

Consultation with colleagues and second opinions are always options. It is also important to consider the option of extended turnout. Because the career of a polo pony can last 12 to 15 years, owners are often willing to give the horse 6 to 12 months of turnout to avoid any further injury. If subtle lameness resolves with phenylbutazone therapy, the polo pony can compete because there is no drug testing in polo competition. However, this option must be elected with caution.

Several lameness problems may exist simultaneously in a polo pony, a fact that makes observing the primary or baseline lameness difficult. Subtle signs such as the failure of a horse to stop appropriately, a horse that jumps on after stopping, or a horse that turns one way or the other when stopping (which is probably from outside hindlimb pain; horses turn away from lameness) may reflect low-grade lameness. If these observations have been made, having the horse ridden to witness the problems first hand is useful. In one author's experience (PJM), the most common source of pain in this type of situation is from the distal hock joints.

IMAGING CONSIDERATIONS

Conventional, computed, and digital radiography are the mainstays of imaging, with the front feet and front fetlock joints and hock joints being examined most frequently. The introduction of computed and digital radiography has provided great advantages because, with the exception of faulty positioning or movement, obtaining nondiagnostic radiographs is almost impossible. Exposure can be adjusted at the time of processing, and subtle details that would have been difficult to see on conventional radiographs can now readily be detected and scrutinized easily with computed and digital radiography. Images can be enlarged, and the contrast and brightness can be improved, which are important factors in the diagnosis of incomplete fractures.

Scintigraphic examination is particularly useful in polo ponies with undiagnosed lameness and in those with palmar foot pain, but it is not always helpful in horses with chronic lameness (SK). Motion-correction software has been an important innovation.

Ultrasonography is extremely important in evaluating the damage and healing processes in tendons and the SL in forelimbs and hindlimbs. Transverse images are used more frequently in identifying lesions, whereas longitudinal images aid in assessing healing. Ultrasonographic evaluation of the supraspinous ligament is often useful in horses with obscure hindlimb lameness. We have not found thermography particularly useful in our practices.

Magnetic resonance imaging (MRI) has become available in university settings and in some private equine practices. Despite a long learning curve in the interpretation of magnetic resonance images, many differential diagnoses and prognoses have emerged. Nowhere is this more evident than in obscure foot and pastern lameness with no detectable radiological abnormalities.

Diagnostic arthroscopy in horses with OA of the metacarpophalangeal or carpal joints can be valuable in evaluating the condition of joint surfaces. Palmar intercarpal ligament injury has been diagnosed in ponies with lameness localized to the middle carpal joint but lacking

radiological and scintigraphic abnormalities. Tenoscopy and bursoscopy also can be useful diagnostically and therapeutically.

TEN MOST COMMON LAMENESS PROBLEMS IN POLO PONIES

1. Superficial digital flexor tendonitis
2. Metacarpophalangeal osteoarthritis
3. Proximal palmar metacarpal pain and suspensory desmitis
 - a. Proximal suspensory desmitis and third metacarpal bone disease
 - b. Body suspensory desmitis and splint bone disease
 - c. Suspensory branch desmitis and sesamoiditis
4. Injury to the hoof and distal phalanx
5. Palmar foot pain including navicular disease and deep digital flexor tendonitis
6. Distal interphalangeal joint osteoarthritis
7. Desmitis of the accessory ligament of the deep digital flexor tendon
8. Splint bone disease
9. Distal hock joint pain
10. Gluteal myositis and back pain

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

SDF tendonitis is the most common soft tissue injury seen in polo ponies and is by far the most common reason for early retirement. SDF tendonitis can be divided into three categories by location on the limb—high (proximal), mid-metacarpal, and low (distal)—or by cause: trauma, speed, and fatigue.

We believe that most peripheral injuries of the SDFT result from tendon trauma while the limb is bearing weight. However, the Editors note that peripheral injuries commonly are seen in other sports horses, such as Standardbred racehorses and reining horses, in which direct trauma is usually not a factor. These injuries occur much more frequently at the midmetacarpal region on the lateral aspect and to a lesser extent on the palmar surface of the tendon (Figure 119-3). Proximal SDF tendonitis also can be caused by trauma (PJM). These areas have a high degree of exposure to swinging mallets and flying hooves. Despite new protective boots, the SDFT is still traumatized with surprising frequency. Traumatic tendon injuries are generally noticed 1 to 2 days after the incident and are characterized by a slight widening of the tendon (not a banana-shaped profile). Lameness is usually not present, but the area is warm and tender to palpation. Some horses have recurrent heat and swelling that resolves quickly with topical and systemic antiinflammatory therapy. Peripheral tendon fiber lesions may involve 20% or less of the cross-sectional area (CSA) of the tendon. However, careful ultrasonographic examination of the medial and lateral borders of the SDFT and critical evaluation of longitudinal images are necessary. Recurrent tendonitis leads to typical swelling and later lameness commonly found with moderate or severe SDF tendonitis.

Core lesions and lesions of the SDFT adjacent to the DDFT are thought to be injuries related to speed and fatigue. Hard, fast ground may be a predisposing factor. SDF tendonitis may result in a banana-shaped profile of the

Fig. 119-3 • Transverse ultrasonographic image of the palmar metacarpal region of a polo pony with traumatic tendonitis of the lateral aspect of the superficial digital flexor tendon (arrow). Lateral is to the left. After initial diagnosis, the horse continued to play, and the lesion progressed.

metacarpal region. Core lesions compromising between 20% and 25% of the CSA of the SDFT are serious, and the risk of recurrence is high (Figure 119-4). Horses with small CSA tears that extend more than 2.5 cm in length or those with distally located tendonitis involving SDFT impingement by the palmar annular ligament (PAL) are at high risk of recurrence. Despite appropriate therapy, these horses often have chronic and recurrent lameness, and ultrasonographic evaluation reveals a lesion that often fails to heal.

Initial therapy for any polo pony with tendonitis regardless of location or cause includes the application of ice boots and cold-water hosing, sweats, and compression wraps, as well as the administration of NSAIDs. A combination of injection and rest or surgical management has been successful (MWR).

Medical Management

Peritendonous injections over lesions and intralesional injections have become the mainstay of today's preferred therapy for SDF tendonitis. The aim of this therapy is to return the injured segment of tendon to its elastic state and maintain tensile strength. Peritendonous injections of short-acting corticosteroids and hyaluronan may help to reduce inflammation and improve the cosmetic appearance of the tendon profile, but it is important that corticosteroids are not injected directly into a tendon. Peritendonous corticosteroid injection is frowned on in the United Kingdom (PJM). Autologous adult mesenchymal stem cells, platelet-rich plasma (PRP), and porcine bladder matrix (PBM) have emerged as the biological-based therapies of choice and have markedly increased the success of medical management. One author (PW) prefers an ultrasonographic guided injection of PRP directly into lesions and prefers to use only small volumes of the prepared serum into the

Fig. 119-4 • Initial (A) and 40-day follow-up (B) transverse ultrasonographic images of the palmar metacarpal region of a polo pony with a typical core lesion of the superficial digital flexor tendon. Tendon splitting was done immediately after the initial image was obtained. The core lesion is more echogenic in the follow-up image but can still be seen.

lesion. Results using adult fat-derived stem cells are equally satisfactory, but this technique requires preinjection surgical collection, as well as transit time, and is substantially more expensive than using in-house processed PRP. PBM is commercially available (ACellVet, ACell Inc., Columbia, Maryland, United States), requires no surgical harvesting or transit time, and is comparable in price to PRP processing, although it occasionally causes postinjection flares. These flares can be reduced by using a small volume of PBM rather than using the entire reconstituted vial. Daily topical icing and rebandaging, along with NSAIDs, are good precautionary therapies to reduce reactions.

Ultrasonographic assessment of tendons 2 months after injection with one of these biologically based products has

revealed remarkable filling within hypoechogenic lesions on transverse images. At 6 months after treatment there is good fiber alignment seen on longitudinal images. The real endorsement of success is that approximately 80% of horses with first-time bowed tendons treated with these products have returned to the same level of polo without recurrence of injury within 8 to 12 months.

Surgical Management

Tendon splitting is now seldom used as a standalone therapy to manage polo ponies with SDF tendonitis. If used, tendon splitting within 1 week after injury appears to be beneficial in decompressing the lesion. Tendon splitting must be done early because granulation tissue forms quickly and cannot be decompressed. After appropriate sedation, perineural analgesia, and aseptic preparation, 30 to 40 incisions with a No. 11 scalpel blade in a stabbing manner (a fan-shaped pattern is avoided) are used to decompress only the affected tendon segment. One author prefers using a double-edged tenotome in a fan-shaped pattern (MWR). The procedure can be performed with the limb in a weight-bearing or flexed position, but a weight-bearing position is preferred. With experience, the texture of diseased tendon can be differentiated from surrounding normal tendon structure. Bandages are applied, and horses are confined to a box stall and given controlled, increasing handwalking over the next 8 to 10 weeks. Controlled exercise is recommended for a minimum of 4 to 6 months before any form of turnout exercise is given, but client compliance with this timetable is poor unless a horse walker is available. Unfortunately, most horses are turned out to pasture after blistering within 1 month of injury, a conventional practice we believe is harmful to tendon healing. Total time of turnout exercise (after controlled exercise) is 8 to 12 months. Follow-up ultrasonographic evaluation is important to monitor healing and to determine when exercise level can be stepped up. Desmotomy of the accessory ligament of the SDFT (superior check desmotomy) has been useful in horses with large core lesions (CSA >25%) and in those with small tears (CSA <15%) that are more than 2.5 cm in length. Combining the surgical procedures of desmotomy and tendon splitting early after injury has been successful in returning horses with tendonitis of the SDFT to polo. After surgery, horses are given stall rest and handwalking for 4 to 6 weeks, with a total of 4 to 6 months of controlled exercise, before being turned out or conditioned for polo. Desmotomy of the PAL occasionally is performed when the SDFT is injured and enlarged just above the ligament. This surgery interrupts a self-perpetuating cycle of injury that develops between the enlarged tendon and the thickened PAL. One author (PW) believes that horses with distal tendonitis of the SDFT involving the PAL should initially be treated with peritendinous injection of short-acting corticosteroids followed by compression wraps, not only to reduce the size and improve cosmetic appearance of the SDFT but also to prevent the need for desmotomy of the PAL.

The most common reasons for therapeutic failure in horses with SDF tendonitis are lack of ultrasonographic follow-up evaluation after tendon splitting to determine whether additional therapy is needed, poor owner compliance concerning walking the horse and stretching the injured tendon in the early stages of healing, not allowing

for adequate rest before the horse is returned to work, and failure to perform ultrasonographic examination at the time of initial injury, resulting in an inability to evaluate maximal medical improvement before returning the horse to unsupervised work.

METACARPOPHALANGEAL (FETLOCK) OSTEOARTHRITIS

OA of the fetlock joint is the most common articular problem in polo ponies and the most common articular problem necessitating early retirement. Former racehorses with mild OA, osteochondrosis, chip fractures, and chronic capsulitis may be sold for use as polo ponies and have a high risk of redeveloping lameness. The fetlock region of any polo pony with forelimb lameness should be examined carefully. Lameness apparently originating from the fetlock joint based on the clinical observations of pain on palpation, decreased range of motion, and a positive response to distal limb flexion must be differentiated from suspensory branch desmitis and splint bone disease. Intraarticular analgesia is important for differentiation. A full set of radiographs should be obtained. One author (PJM) recommends using large cassettes to assess the fetlock joint and distal aspect of the splint bones. Common radiological findings include fragmentation of the dorsoproximal aspect of the proximal phalanx (Figure 119-5), radiolucent areas in the distal aspect of the McIII, proliferative new bone formation on the palmar aspect of the PSBs, and mineralization of the proximal and distal fetlock joint capsule attachments (Figure 119-6).

Intraarticular injections are the mainstay of treatment. One author (PW) injects both short-acting corticosteroids and hyaluronan. Another author (PJM) prefers polysulfated glycosaminoglycan (PSGAG; Adequan, Luitpold Animal Health, Shirley, New York, United States) therapy or short-acting corticosteroids and hyaluronan or a combination of atropine, short-acting corticosteroid, and hyaluronan. Intramuscular injections of PSGAGs at biweekly intervals for 1 month and then possibly weekly for the entire season

are recommended. Horses that do not respond well to intraarticular injections of corticosteroids may be candidates for serial interleukin-1 receptor antagonist protein (IRAP) injections or arthroscopic evaluation because many of these horses have considerable cartilage damage. IRAP is now commercially available for in-hospital collection, incubation, and administration and is generally administered at bimonthly intervals for a series of three to five doses. IRAP was initially used by one author (PW) in polo ponies that were unresponsive to corticosteroid therapy and was used in conjunction with hyaluronan. Unless the IRAP is prepared with strict asepsis and processed preferably in a sterile hood, it is well advised to use a 2- μ m filter to ensure sterility during the injection process. If using hyaluronan in conjunction with the IRAP, be sure to inject the hyaluronan either first or after the filter is removed from the needle hub because the viscosity of the hyaluronan is too thick to pass through the filter. Now many veterinarians, including one author (PW), are using IRAP as their first line of therapy to treat both acute and chronic joint disease, and its good success tends to appear later rather than earlier in the life of an osteoarthritic joint. Daily icing, poulticing, and NSAID administration can help reduce inflammation in horses with chronic OA. In horses with chronic OA, radiological abnormalities may be extensive, but many horses are serviceably sound (Figure 119-7).

Fetlock joint capsulitis is often a concurrent problem with fetlock OA and can be an additional source of pain and a cause of restricted motion. On rare occasions it can be the only cause of pain and resentment of joint flexion. One author (PW) has seen substantial benefit from mesotherapy applied to the dorsal aspect of the fetlock joint. After aseptic preparation and performing a "ring block" of the fetlock joint, the author uses a 3-tipped mesotherapy injector with 27-gauge \times 4-mm needles to inject the area with corticosteroid (triamcinolone acetonide, 9 mg), Sarapin (4 mL), and mepivacaine (4 mL) dorsomedially and dorsolaterally. A compression wrap/sweat is applied for 24 hours after the injection. This treatment usually results in greater range of pain-free motion of the joint and may also be used in conjunction with intraarticular therapy.

Fig. 119-5 • Dorsolateral-palmaromedial oblique radiographic image of a metacarpophalangeal joint of a polo pony with osteoarthritis. Soft tissue swelling is apparent; a rounded osteochondral fragment is on the proximal dorsomedial aspect of the proximal phalanx; and proliferative changes involve the proximal aspect of the proximal phalanx and proximal sesamoid bones.

Fig. 119-6 • Slightly oblique lateromedial radiographic image of a metacarpophalangeal joint. Mineralization at the insertion of the lateral digital extensor tendon and metacarpophalangeal joint capsule on the proximal aspect of the proximal phalanx is a common radiological finding in polo ponies with osteoarthritis of the fetlock joint. Although the finding is important, it does not preclude successful playing.

Fig. 119-7 • Lateromedial radiographic image of the distal aspect of a forelimb of a serviceably sound polo pony. There is modeling of one of the proximal sesamoid bones (and a mineralized radiopacity distally) and the dorsoproximal aspect of the proximal phalanx, as well as osteoarthritis and osteochondral fragmentation of the proximal and distal interphalangeal joints.

Chronic proliferative synovitis (villonodular synovitis) is common in polo ponies with chronic OA of the fetlock joint and may be associated with capsular tearing (SK). The dorsal aspect of the fetlock joint develops an apple-shaped appearance, with only mild or moderate effusion. Chronic proliferative synovitis is most common in horses previously used as racehorses and becomes evident after several years of polo. Radiographs may reveal an abnormal contour of the distal dorsal aspect of the McIII, and positive contrast radiographs may be diagnostic. We prefer ultrasonographic examination because ultrasonography helps differentiate between horses that are surgical and nonsurgical candidates. Chronic proliferative synovitis masses of 1.5 cm or larger should be removed arthroscopically to maximize long-term prognosis, whereas horses with smaller masses respond well to rest and intraarticular corticosteroid injections. Intraarticular atropine sulfate also has been used successfully (SK) to reduce effusion.

SUSPENSORY DESMITIS

Suspensory desmitis is seen at three levels: PSD, suspensory body desmitis, and suspensory branch desmitis.

Proximal Suspensory Desmitis

PSD occurs frequently, and diagnosis is confirmed using high palmar or lateral palmar analgesia. PSD results from

polo ponies exercising on soft, uneven footing and is not necessarily related directly to playing polo. Lameness is usually only visible at a trot and varies in degree. The cranial phase of the stride is shortened, and lameness is usually most prominent with the affected limb on the outside of a circle. Palpation of the proximal palmar metacarpal region often reveals neither pain nor clinically appreciable enlargement of the SL. Polo ponies with PSD often fail to improve with rest and NSAID administration. Longitudinal ultrasonographic images are most useful in the diagnosis of PSD, but negative ultrasonographic findings do not necessarily eliminate the possibility of injury. MRI is useful to evaluate the bone–ligament interface, particularly in horses in which PSD is difficult to diagnose because there are no detectable changes on radiographs or on ultrasonographic images. CSA measurements on transverse images are occasionally helpful if the same area is measured in the affected and contralateral limbs. One author (PW) has found that variation in CSA measurements leads to misdiagnosis because even in normal polo ponies obtaining reliable repeat measurements is difficult. Hypoechoic muscle tissue should not be confused as a lesion (SK).

PSD causes more subtle lameness and clinical signs in polo ponies than in other sports horses. Subtle injury and enlargement may cause the ligament to be pinched or compressed by overlying dense fascia, especially in hindlimbs. Horses with long-standing PSD often have increased radiopacity of the proximal aspect of the McIII visible in lateromedial or dorsopalmar radiographic images. Absence of increased radiopacity does not rule out PSD because horses with soft tissue injuries often lack bony involvement. Avulsion fractures of the McIII at the origin of the SL, incomplete longitudinal fractures of the McIII, and stress reaction can occur independently or concomitantly to PSD. Radiological and ultrasonographic examinations may reveal small or large fragments or proliferative changes and radiolucency associated with the palmar cortex of the McIII. Computed and digital radiography, nuclear scintigraphy, and MRI are beneficial in diagnosing bony injury and differentiating it from PSD. Follow-up radiographs may be necessary because avulsion or longitudinal fractures may not show up on initial radiographs.

Even without treatment, almost all polo ponies with PSD and bony causes of proximal palmar metacarpal pain recover within a 3-month rest period. However, horses that are notably lame at a walk, stand somewhat unstably, and occasionally buckle at the carpus of the affected limb may require up to 6 months of rest. In polo ponies with PSD in which a quick return to work is mandated, local injection into and around the origin of the SL with a combination of short-acting corticosteroids and PSGAGs hastens resolution of clinical signs. Ponies are walked for 1 week and then put in light work the second week. By the third week they may be galloped and are able to play shortly thereafter. Owners tend to keep polo ponies with PSD in work if the end of the season is near because ponies are turned out routinely for 3 to 6 months after the season. Owners may gamble successfully by continuing to play the horse through the end of the season without permanently damaging the ligament. Polo ponies rarely get hindlimb PSD, but when they do, prognosis is guarded, and treatment by neurectomy often is required.

In horses with chronic PSD, once bony involvement has been ruled out, local injections of corticosteroids and Sarapin or internal blister may be warranted. In the United Kingdom and Europe, injection of corticosteroids into the proximal aspect of the SL is frowned on because this medication may slow healing and may mask the presence of fractures (SK and PJM). This is especially true in horses with acute injuries. Numerous applications of shock wave therapy are popular and may prove beneficial. Horses with known bony injury should be given rest. One author (PW) prefers the use of concentrated bone marrow–derived stem cells to infiltrate the origin of the SL in combination with fasciotomy.

Body Suspensory Desmitis

Body suspensory desmitis is a serious and often career-ending injury. Diagnosis is straightforward if the SL is thickened and painful. Ultrasonographic examination is crucial in assessing SL damage, but radiology is important to evaluate the medial and lateral splint bones because splint bone disease often is associated with suspensory desmitis in a polo pony. Radiographs should be obtained even if obvious areas of pain or bony and soft tissue swelling associated with the splint bones are absent. Treatment of polo ponies with acute body suspensory desmitis includes immediate application of cold or ice therapy, alternating with topical sweats, and administration of NSAIDs. Periligamentous infiltration of short-acting corticosteroids early after injury improves cosmetic appearance and may minimize adhesion formation between the SL and splint bones. Injections are performed in polo ponies only if the owner agrees the horse is in need of long-term rest. The horse gradually is returned to handwalking in 5 to 7 days and can be turned out after 3 weeks. Intralesional injections of concentrated bone marrow into SL body tears have proven beneficial and successful, and one author (PW) prefers this over PBM and fat-derived adult stem cells. Sclerosing agents (e.g., ethanolamine) injected into the SL may be helpful (SK). Two authors (PW and PJM) believe that long-term box stall rest may increase the chance of adhesion formation. One author (MWR) prefers controlled exercise rather than turnout exercise and believes strongly that turnout exercise is the “antithesis of healing.” Ultrasonographic evaluation of ligament healing is important. One author (PJM) has observed many polo ponies with distal body suspensory desmitis that involves the bifurcation and invariably at least one branch. If desmitis at the suspensory bifurcation is severe, the polo pony may never fully recover. The best results are seen with a combination of periligamentous injections of dimethyl sulfoxide (DMSO) and corticosteroids and long-term rest. Performance level may need to be dropped to junior polo, and even at this level lameness may be persistent or recurrent.

Suspensory Branch Desmitis

Suspensory branch desmitis is common in polo ponies. The lateral branch is injured more frequently than the medial branch, and occasionally both branches are injured simultaneously. Pivoting of the distal limb at high speeds is likely the cause of suspensory branch desmitis. Faulty conformation is another important predisposing factor. Horses that are toed in tend to develop lateral suspensory branch desmitis, whereas those that are toed out tend to develop

Fig. 119-8 • Dorsolateral-palmaromedial oblique radiographic image of a metacarpophalangeal joint, with mineralization in the lateral branch of the suspensory ligament at the attachment to the proximal sesamoid bone (arrow). Note also the soft tissue swelling.

medial suspensory branch desmitis. Palpation of the branches while the fetlock joint is in partial flexion is a preferred technique of one author (PW). Firm palpation and lower limb flexion followed by trotting exacerbates the degree of lameness. Ultrasonographic examination of the branches is accomplished easily and allows assessment of the degree of suspensory branch desmitis. Radiography should be performed to evaluate the distal aspects of the splint bones because fracture and fracture displacement are common in ponies with suspensory branch desmitis. Mineralization in a branch close to attachment on a PSB may occur in horses with chronic injury (Figure 119-8). Horses with acute injuries are treated identically to those with suspensory body desmitis. The appearance of the branch can be restored cosmetically to near normal over time with periligamentous injection of short-acting corticosteroids. The branch can be split 2 to 3 weeks after injury, although results in the United Kingdom have been disappointing (SK). In the United States, one author (PW) believes that branch splitting in conjunction with shock wave therapy has had superior results compared with adult stem cell or PRP injections. Horses with suspensory branch desmitis need about 6 months of layup time before returning to polo training. One author (PJM) believes that adhesions between the inflamed branch and surrounding tissue or the ipsilateral splint bone negatively influence prognosis, and corticosteroid injections may limit adhesion formation. Surgical adhesiolysis and distal ostectomy of the fractured splint bone may be useful in horses with chronic suspensory branch desmitis and splint bone fracture, but the cosmetic appearance is usually less than desirable. Counterirritants still are used in Europe with variable results. We believe that pin firing (hot firing) is not successful for horses with suspensory body desmitis, but it can be useful for horses with suspensory branch desmitis as a last resort.

INJURY TO THE HOOF AND DISTAL PHALANX

Polo more than other types of equine sporting activity predisposes horses to direct hoof trauma. Direct trauma

results from swinging mallets, horses stepping directly on the hard polo balls used during playing, interference or direct impact from hooves of nearby horses, and from horses stepping on wooden sideboards at great speed. Calk or stud injuries to the hoof wall and pastern region are most common. Careful evaluation of wounds for involvement of deeper structures, such as the PIP and DIP joints, is necessary. A common lameness that occurs during polo competition is called *getting stung*, referring to a sudden crippling lameness, lasting only a few minutes, generally resulting from a blow to the hoof or pastern by a mallet or hoof of another horse. The horse is usually sound within minutes of the incident with no clinical evidence of injury. Occasionally, a fracture occurs that may not be evident radiologically for up to 14 days.

Fractures of the Distal Phalanx

Acute fractures of the palmar processes of the distal phalanx often occur from mallet blows, and because polo is played right-handed, fractures usually are seen in the medial aspect of the left forelimb and lateral aspect of the right forelimb. Oblique fractures are sometimes difficult to see in conventional radiographic images, and several dorsoproximal-palmarodistal oblique images may be necessary. Rarely, fractures of the solar margin or of the extensor process of the distal phalanx are seen. Management of polo ponies with distal phalangeal fractures is similar to that in other sports horses.

PALMAR FOOT PAIN INCLUDING NAVICULAR DISEASE

Palmar foot pain in polo ponies with TB and TB-cross ancestry appears to be decreasing, primarily because of the successful efforts of farriers and owners. The problem may be worse in American TBs than in TBs originating from the United Kingdom, Argentina, Australia, and New Zealand (PJM). The long-toe and underrun heel complex and the tendency to shoe front feet with shoes with short branches that sit tight at the heel (to prevent front plates from being pulled off by hind feet) gradually have been corrected. Squared or rolled toe shoes, with or without an elevated heel (world plates and natural balance plates), have reduced the number of polo ponies with broken pastern foot axes and have reduced DDFT tension caused by prolonged breakover. Owners have allowed farriers to reset polo plates more frequently during the playing season and to perform more frequent four-point trims during the off-season than in previous years. The causes of palmar foot pain are often difficult to differentiate from navicular disease because the horse may show a painful response to hoof testers, and lameness is abolished using palmar digital analgesia. Differentiation may be possible using intraarticular analgesia of the DIP joint, radiography, and scintigraphy. Many polo ponies with palmar foot pain have secondary pain at the origin of the SL, which is thought to be caused by alteration of gait.

A common source of palmar foot pain is laminar tearing at the heel. Sudden stops force the horse to use the heels of the front feet as brakes. Corns or heel bruising can cause poor performance and lameness. Corns are diagnosed easily using hoof testers and by carefully inspecting the seat of the corn for hemorrhage or discoloration. One

author (PJM) has seen many polo ponies toward the end of the polo season with bilateral, biaxial horn staining resembling chronic corns that apparently did not result in overt lameness. Management of polo ponies with palmar foot pain resulting from corns is similar to that used for undiagnosed palmar foot pain, including the application of wedge pads to relieve heel pain for a few games, or by using the four-point trimming method with natural balance or straight bar shoes and acrylic rubber frog and heel support. One author (SK) has found that four-point shoeing provides poor grip and traction and considers it unsuitable for polo ponies. However, most feel these shoeing techniques appear to decrease stress on the heel and the DDFT and navicular region. Hoof growth stimulants and NSAID administration may help horses with palmar foot pain.

Osteitis of the Distal Phalanx (Pedal Osteitis)

Although definition and accurate diagnosis of osteitis of the distal phalanx remain obscure, many polo ponies with palmar foot pain have evidence of disease in the margins of the distal phalanx on scintigraphic and radiographic images. There may be new bone projecting distally from the palmar aspect of the distal phalanx seen on a lateromedial radiographic image. This finding should be interpreted carefully on radiographs obtained during purchase examinations.

Navicular Disease

Navicular disease in a polo pony is characterized by chronic forelimb lameness, which is abolished using palmar digital analgesia, intraarticular analgesia of the DIP joint, or analgesia of the navicular bursa, often with little radiological abnormality. Nuclear scintigraphy may be helpful to differentiate navicular disease from other causes of palmar foot pain. Most horses with early navicular disease respond positively to intraarticular administration of hyaluronan and corticosteroids into the DIP joint. The administration of NSAIDs and isoxsuprine and the application of corrective shoeing techniques (see [Palmar Foot Pain](#) section) are valuable. Those ponies unresponsive to intraarticular injections of the DIP joint may improve after injection of the navicular bursa, best performed under radiographic guidance. MRI has become extremely valuable in differentiating between navicular bone pathology and soft tissue pathology. Therapy, length of rest, and prognosis differ for horses with deep digital flexor (DDF) tendonitis versus those with acute navicular bone pain. Horses with acute navicular bone injury that fail to respond to treatment of the DIP joint or navicular bursa are rested for 3 to 6 weeks and treated with NSAIDs; work is then resumed for the rest of the season with continued treatment with NSAIDs. Horses with advanced navicular disease or those unresponsive to therapy may be dropped from medium- or high-goal polo. Horses with DDF tendon (DDFT) injury have a much more guarded prognosis and are treated by 6 to 12 months of rest. Initially a frog support is applied and the heel is elevated, combined with stall rest, handwalking for 4 weeks, and NSAIDs. This is followed by 3 months of shoeing with full heel support and then turnout unshod, with monthly trimming for the remainder of the convalescent period. Palmar digital neurectomy is considered undesirable and is not routinely performed. Chemical neurolysis (long-term foot block) is of limited value. Cryoneurectomy can give limited relief,

but the palmar digital nerves regrow and lameness recurs. Concomitant or solitary injury of the DDFT does not appear to be as common in polo ponies as in other sports horses (PJM). Shock wave therapy may offer a viable solution for these horses.

DISTAL INTERPHALANGEAL OSTEOARTHRITIS

Early (synovitis) and chronic OA of the DIP joint can cause lameness in the polo pony, but diagnosis can be challenging because of the lack of specificity of analgesic techniques in the foot. For example, if more than 6 mL of local anesthetic solution is injected into the DIP joint and lameness is evaluated after 3 to 5 minutes (SK) or 10 minutes (PW), pain from other areas of the foot, including the sole, can be blocked inadvertently. This effect can be avoided by using smaller amounts of local anesthetic solution. Horses with synovitis have DIP joint effusion and manifest only a mildly painful response to lower limb flexion. However, this test may be positive in horses with many sources of pain, including either the navicular bone or the fetlock joint. Management of horses with OA of the DIP joint usually includes intraarticular medication. Short- or long-acting corticosteroids are preferred to injection with hyaluronan. One author (PJM) combines corticosteroids and DMSO because DMSO may improve distribution of corticosteroids to all parts of the joint and the navicular bursa. The DIP joint is the only joint in which one author (PW) uses PSGAGs, combined with short-acting corticosteroids. Another author (PJM) favors using PSGAGs in horses unresponsive to injections with corticosteroids. Most of these horses have clinical and radiological evidence of advanced OA. In some polo ponies, lameness does not improve directly after intraarticular analgesia but inexplicably resolves 24 to 36 hours later, when presumably the effects of the corticosteroid begin. After intraarticular injection, horses are given 3 weeks of limited exercise and a tapered dose of NSAIDs. Weekly intramuscular administration of PSGAGs for a minimum of 30 days and the application of corrective shoes to ease breakover are recommended.

DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON

Trainers and owners commonly confuse chronic desmitis or acute tears of the accessory ligament of the deep digital flexor tendon (ALDDFT) with bowed tendons. Desmitis of the ALDDFT occurs in polo ponies, especially older ponies (SK), but is less frequent than SDF tendonitis. Mild desmitis is characterized by a meaty, nontender swelling of the proximal palmar metacarpal region between the SL and DDFT. Horses with severe or complete tears can have prominent swelling at or near the junction of the ALDDFT with the DDFT, but neither lameness nor the response to palpation is commensurate with the degree of damage. Diagnosis must be confirmed and healing monitored using ultrasonographic examination. Initially, horses are managed with rest, cold therapy including ice, application of sweats, and administration of NSAIDs. Local infiltration of short-acting corticosteroids around (but not in) the ALDDFT can help cosmetic appearance. Stall rest for 2 weeks is recommended, and thereafter horses can be turned out for 4 to 6 months. Follow-up ultrasonographic examination reveals

an enlarged, hyperechogenic ALDDFT. Prognosis for future soundness and return to polo is usually excellent in horses with small (<30% mass) tears, but swelling persists. Chance of recurrence is slim. In horses with large tears (>30% mass) or near ruptures, the chance to return to competitive polo is slim, even with 1 year off work.

SPLINT BONE DISEASE

Traumatic exostoses (Figure 119-9) caused by swinging mallets and fractures of the splint bones are common in polo ponies and are sometimes referred to as *bamboo fever*. Although trauma is usually the inciting cause of exostoses, injury of the SL may play a role (PJM). Horses with splint exostoses resent direct palpation, but many do not manifest overt signs of lameness. If lameness is present but the exostosis is only mildly painful, a splint block (see page 1152) should be performed to confirm the diagnosis. Splint disease can make a veterinarian look foolish because an acute injury may be confused with PSD, but subsequent development of a large golf ball-size swelling reveals the true diagnosis. Oblique radiographic images are most helpful for evaluating the splint bones.

Local infiltration of corticosteroids and Sarapin is used to treat polo ponies with acute splint exostoses. Other injections include a combination of corticosteroids, Sarapin, calcitonin, and medroxyprogesterone acetate. Calcitonin (400 IU) and medroxyprogesterone acetate (200 mg) are used commonly in Europe (PJM). Rest, compression wraps, sweats, and the administration of NSAIDs are useful. Polo ponies with chronic exostoses seem to benefit from pin freezing (cryotherapy), and this is the treatment of choice, with a quick return to work in 14 days. Cryotherapy appears to stimulate remodeling of chronic proliferative splint exostoses, and often a cosmetically acceptable limb profile is seen within 6 months. Despite the resulting white spots, clients seem to accept this form of therapy because of a high success rate. Thermocautery (hot firing) has merit, and early results of shock wave therapy appear promising (PJM).

Fig. 119-9 • Dorsolateral-plantaromedial oblique radiographic image of the metatarsal region. There is a comminuted fracture of the proximal aspect of the fourth metatarsal bone caused by mallet injury (called bamboo fever). This fracture usually does not require internal fixation, and prognosis for future soundness is good.

Proximal splint bone fractures may require surgical fixation, and certainly horses need prolonged stall rest and a slow return to work. If fractures are nonarticular and fragments are not displaced or are displaced minimally, prognosis is favorable.

Polo ponies with nondisplaced diaphyseal splint bone fractures respond well to cryotherapy. Cryotherapy not only produces local analgesia but also induces deep fibrous tissue formation that stabilizes fracture fragments. Cryoprobes (No. 17 pointed probes, Veterinary Ophthalmic Specialties, Inc., Moscow, Idaho, United States) are applied two at a time in firm contact with the skin covering the abnormal splint for 1 minute at each site, at sites 1.5 cm apart. Applying two probes at different sites simultaneously decreases treatment time. Preselected aim point patterns for pin freezing are marked by commercially available office white correction fluid. Because each site is to be frozen only once to minimize surface skin necrosis, technicians often draw the pattern on a piece of paper before freezing and check off the appropriate sites once the probes have been applied. A major reason for failure of pin freezing splints is the use of cryospray units to apply nitrogen, rather than using prefrozen probes. Pointed probes pressed firmly into the skin form better ice balls on the surface of the bone, creating a much better bone response, remodeling, and flattening of the exostosis. Maintaining a 1-minute freeze with no movement of the subzero probes is also useful. Failure to pattern the pin freeze outward to slightly beyond the perimeter of the preexisting splint exostosis often results in continued growth of the exostosis above and below the therapy area. After cryotherapy, the limb is kept wrapped for up to 3 weeks, but ponies return to exercise within 4 to 7 days. Ponies with nondisplaced splint bone fractures are given rest for 4 to 6 weeks. Distal splint bone fractures can be diagnosed easily using longitudinal ultrasonographic images or radiography. These fractures usually are associated with chronic suspensory branch desmitis, which is thought to cause bowing of the distal aspect of the splint bone and subsequent displacement and proliferative changes (Figure 119-10). Distal fracture fragments generally are removed surgically, and concomitant splitting of the involved SL branch(s) is often performed.

DISTAL HOCK JOINT PAIN

Polo ponies can play successfully with moderate to severe radiological changes in the distal hock joints (Figure 119-11). Most of the distal hock joint pain appears to be subclinical, meaning lameness is not the most noticeable clinical sign. Most polo ponies with distal hock joint pain are noticed by owners or riders to lack quick jump-out speed and the ability to stop abruptly and are noticed to be running through the bridle. These ponies generally improve if they are given ample warm-up time before playing. Distal hock joint pain appears to be one source of pain with which a polo pony can live, but such pain is a major cause of poor performance and may induce compensatory lameness such as PSD in the forelimbs as a result of overload. Proximal limb flexion tests may elicit little response, and detecting pain or effusion using careful palpation is difficult in some horses. Because lameness is not necessarily proportional to radiological changes, scintigraphic examination is helpful,

Fig. 119-10 • Dorsolateral-palmaromedial oblique radiographic image of the metacarpal region. A chronic displaced fracture of the fourth metacarpal bone is associated with suspensory branch desmitis. The second metacarpal bone is bowed away from the third metacarpal bone; chronic proliferation has resulted from instability; sesamoiditis is apparent; and the suspensory branch has mineralization.

Fig. 119-11 • Dorsomedial-plantarolateral oblique radiographic image of a left hock with radiological evidence of advanced osteoarthritis. This polo pony was not lame.

especially in polo ponies with subtle hindlimb lameness. Diagnostic analgesia is an important tool if lameness is perceptible, and in horses with bilaterally symmetrical lameness, analgesia of one hindlimb may induce obvious contralateral lameness. Combining diagnostic and therapeutic injections is commonplace because the practice saves time and money. The tarsometatarsal and centrodiscal (distal intertarsal) joints are injected most commonly with methylprednisolone acetate, but in some ponies the tarso-cruial joint also is injected. Intramuscular administration of PSGAGs and intravenous injection of hyaluronan throughout the playing season appear to be helpful in allowing horses to play up to potential. Horses are kept in work and placed on low doses of NSAIDs throughout the season, and training is limited.

GLUTEAL MYOSITIS AND BACK PAIN

Gluteal myositis often accompanies subclinical hindlimb lameness and is often a compensatory problem. One or both hindlimbs have a shortened cranial phase of the stride. Deep palpation of the gluteal muscles elicits pain, although the muscles never feel as hard as they do in ponies with rhabdomyolysis. If possible, it is important to determine whether gluteal myositis is a primary or secondary problem. Gluteal myositis can be differentiated easily from rhabdomyolysis because serum creatine kinase and aspartate transaminase levels are invariably normal. Polo ponies with gluteal myositis can be treated with local injections directly into the gluteal muscles and between the biceps femoris and semitendinosus muscles. The horse is allowed light work and is placed on NSAIDs. One author (PW) has had modest success using a 5-day series of rubeola virus immunomodulator. If gluteal myositis is secondary, the primary source of pain must be identified and managed successfully.

Back pain in polo ponies is often secondary to lameness or results from mismanagement, including use of ill-fitting saddles, overweight amateur riders, and mouth problems. Poor dentition from lack of, or inappropriate, tooth floating procedures causes sharp molars to come in contact with gag bits. Horses carry the head and neck high to avoid pain and tend to hollow the back. Back pain can become a permanent or chronic problem if horses are mismanaged continually. Back pain generally is characterized by a painful response to palpation along the lateral edges of the longissimus dorsi muscles. The horse exhibits a crouching gait when mounted and during initial walking under saddle.

Intramuscular injections of corticosteroids combined with Sarapin (2:1 ratio) are performed along the length of the longissimus dorsi muscle, from the caudal border of the trapezius muscle to the level of the tuber coxae, 15 cm lateral to the dorsal midline. Injection sites are placed every 15 cm, and 5 mL of the mixture is administered at each site. Mesotherapy is also extremely beneficial and is often used in conjunction with deep muscle injections. After preparation of the lumbar region, mesotherapy is performed using a 5-tipped mesohead with 27-gauge \times 4-mm needles. A volume of 35 mL of flumethasone, Sarapin, mepivacaine, and Traumeel is used to inject two passes down each side of the dorsal midline. Generally horses are ponied (led from another horse) for 5 days before being ridden. Relief from

pain is quick and predictable with this treatment. Because back pain may be compensatory to primary distal hock joint pain or other lameness, it is important to evaluate the hindlimbs and pelvis carefully. Primary management of the distal hock joint pain and local treatment of acupuncture points in the back are common.

Dorsal spinous process impingement can be a source of back pain, and one author (PJM) believes this is a major cause of back pain in the polo pony. Diagnosis should be confirmed by assessing the effect of local analgesia and/or performing scintigraphy (SK). Treatment involves injection of the spaces between the dorsal spinous processes with corticosteroids and Sarapin. Shock wave therapy may be beneficial (PJM and PW). Horses with back pain are given NSAIDs and are kept fit during a 4- to 6-week period using ponying (being led from another horse) exercise. In Europe, a common management regimen includes paddock exercise as much as possible, lunging exercise with the horse's head down, and little warm-up before polo games. Internal blisters have been used with some success, but care must be taken when injecting these compounds because deep muscle abscesses can develop. Faradism is useful for longissimus dorsi and gluteal muscle strain (SK).

OTHER CONDITIONS

Dislocation (Luxation) of the Superficial Digital Flexor Tendon

Although rare, avulsion injury and dislocation of the SDFT from the tuber calcanei is seen nearly once each year in a busy polo pony practice, resulting in extreme panic by the pony, necessitating sedation. The SDFT usually dislocates laterally, but diagnosis may be difficult before swelling develops. In our experience, surgical techniques, including primary repair, mesh augmentation, and laterally located screws combined with full-limb cast application, are neither successful nor necessary. Most horses respond well to confinement in a small pen and subsequent turnout for 6 to 12 months. Turnout exercise is recommended as soon as possible. Despite the fact that the SDFT remains displaced, causing a slight mechanical lameness and enlargement of the calcaneal and gastrocnemius bursae, horses tend to perform well at the canter and gallop, with a fair to good prognosis for medium- and low-goal polo. Some polo ponies with lateral dislocation of the SDFT in one limb develop the same condition in the opposite limb 1 or 2 years later (PJM).

Fractures of the Cranial Thoracic Dorsal Spinous Processes (Fracture of the Withers)

Fracture of the withers is fairly common. Polo ponies are often tied next to each other for long periods, and a frightened horse occasionally rears up and flips over (Figure 119-12), resulting in fractures of the longest dorsal spinous processes at the withers. Often up to four dorsal spinous processes are fractured, with ventral displacement of the fragments resulting in a flattened appearance of the withers. Ponies are usually only mildly painful to palpation but are generally reluctant to lower the head when grazing. The affected horse may travel with a painful, stiff, extended head and neck carriage, and some horses grunt with every

Fig. 119-12 • Polo ponies commonly are tied to rigid bars and in close proximity to each other. Occasionally a polo pony flips over and fractures the thoracic dorsal spinous processes at the withers.

stride. The prognosis for return to polo is excellent after rest for 4 to 6 months, as long as secondary infection does not develop. Special consideration should be given to saddle fit; a croup strap may be necessary to keep the saddle from sliding forward.

Proximal Interphalangeal Osteoarthritis and Other Pastern Region Injuries

OA of the PIP joint (high ringbone) occurs occasionally in polo ponies and is seen most frequently in green horses (generally Quarter Horses or Quarter Horse/TB crosses) playing on rough terrain in the western United States and generally results from irregular footing. Pain originating from the PIP joint is difficult to diagnose in horses with acute disease without radiological changes, but it can be identified scintigraphically. OA of the PIP joint is often difficult to manage, and although motion of this joint is limited, lameness can be inappropriately severe. Rest (60 to 90 days), NSAID therapy, and intraarticular long-acting corticosteroid therapy are recommended.

A common finding in oblique radiographic images of the pastern region is periosteal new bone on the medial aspect of the left forelimb and the lateral aspect of the right forelimb proximal phalanges (Figure 119-13). Because polo always is played right-handed, powerful neck shots always hit the right side of each forelimb. Lameness is usually insignificant and short lived. These radiological changes should not be confused with those resulting from enthesitis at the attachment sites of the distal sesamoidean ligaments. To differentiate OA of the PIP joint from these proliferative changes, intraarticular analgesia or pinpoint perineural or local analgesic techniques should be performed.

Fig. 119-13 • Dorsomedial-palmarolateral oblique radiographic image of the distal aspect of a left forelimb. Proliferative new bone (arrows) along the palmar medial aspect of the proximal phalanx is typical of a mallet injury. Polo is played right-handed, and trauma usually involves the medial aspect of the left forelimb and the lateral aspect of the right forelimb proximal phalanges.

Sesamoiditis

Inflammation (sesamoiditis) of the PSBs can be caused by direct mallet or hoof trauma and by stress-related injury at the suspensory branch insertions. Traumatic sesamoiditis occurs in the medial PSB in the forelimbs from interference injury and in the lateral PSB in the forelimb and hindlimb from mallet trauma. Diagnosis of sesamoiditis is straightforward using radiography and scintigraphy, but ultrasonographic evaluation provides information about the suspensory attachment as well. One author (PJM) believes that shock wave therapy is a promising treatment modality for sesamoiditis.

Fractures of the PSBs are rare, and response to surgery is similar to that of other sports horses. Ponies with fractures of the base of the PSBs rarely return to athletic soundness with or without surgery. Polo ponies with basilar fractures and desmitis of the oblique sesamoidean ligament often can be helped by using shock wave therapy (PJM). An apical fracture of the PSB may be mistaken for mineralization of the suspensory branch. Polo ponies with apical fractures of the PSBs have a good prognosis, provided that SL injury is not concurrent. Horses with apical fractures associated with sesamoiditis and insertional suspensory branch desmitis often have recurrent lameness. It is important to differentiate true fractures from sesamoiditis or a commonly seen radiological abnormality in older polo

ponies, one to three stress lines in the PSBs, which most often are considered incidental changes.

Digital Flexor Tenosynovitis and Desmitis of the Palmar Annular Ligament

Tenosynovitis of the digital flexor tendon sheath (DFTS) is common in polo ponies. Debate exists as to whether this syndrome is caused by desmitis of the PAL or whether the PAL is a passive structure causing only constriction of the inflamed DFTS. The terms *tenosynovitis* and *desmitis of the PAL* are sometimes used synonymously, but tenosynovitis with mild thickening of the PAL is more common than primary desmitis. A normal or slightly thickened PAL can restrict SDFT movement in horses with tendonitis, but this is a separate entity (see page 1153). In polo ponies, desmitis of the PAL can be solitary and diagnosed in horses with healthy digital flexor tendons. It can lead to tenosynovitis or can accompany tenosynovitis. Primary desmitis of the PAL occurs most frequently from interference injury, when a hind foot strikes a forelimb PAL, or from direct mallet trauma. Initial trauma may be minor, but continued trauma can lead to substantial injury (Figure 119-14). Whether primary or secondary, tenosynovitis with thickening and compartmentalization of the DFTS can occur proximal and distal to the PAL. Diagnosis can be made by combining the results of clinical examination and intra-theal analgesia. Ultrasonographic evaluation is crucial and should include dynamic studies in which the digital flexor tendons and DFTS are evaluated for possible adhesions between tendons, DFTS, and the PAL. Concomitant

conditions, such as OA of the fetlock joint, sesamoiditis, and demineralization of the PSBs at the medial and lateral attachments of the PAL, should be assessed radiologically. Initial management is to apply cold therapy and sweats and to administer NSAIDs. Decompression of the DFTS and injection of hyaluronan and corticosteroids then is followed by 3 weeks of stall rest. Tenoscopy is valuable in identifying horses with tendon tears and to perform adhesiolysis. Palmar annular desmotomy in horses with chronic desmitis or in those with chronic tenosynovitis may be helpful. Definitive therapy should be instituted early and aggressively to minimize adhesion formation.

Desmitis of the Distal Sesamoidean Ligaments

Desmitis of the distal sesamoidean ligaments (bowed pastern) is seen occasionally in polo ponies and usually involves the straight sesamoidean ligament. Diagnosis is made by detecting pain and swelling, performing perineural analgesia (palmar nerve blocks at the base of the PSBs), and using ultrasonographic examination.

Polo ponies with recurrent injury may not resent palpation, and ultrasonographic examination is necessary to differentiate this from other injuries. Proliferative changes along the base of the PSBs and abaxial surface of the proximal phalanx (at the insertion of the oblique sesamoidean ligaments) are often seen. These injuries may be career ending and at best are performance limiting. Long-term rest for 6 months is often necessary. Numerous applications of shock wave therapy have shown promise, and some owners request pin firing as a last resort.

Carpal Region Lameness

The carpus is an uncommon source of lameness in the polo pony. Preexisting chronic radiological changes are often incidental findings, even in horses with reduced range of carpal flexion and mild effusion. Carpal chip fractures can occur, but they are unusual. Tearing of the medial palmar intercarpal ligaments can cause lameness. Transient traumatic carpalitis occasionally is seen after direct trauma from a mallet or ball. Rupture of the carpal sheath is a rare cause of lameness in the polo pony; one author (PJM) has seen two horses with massive swelling in the distal aspect of the antebrachium, and ultrasonographic evaluation revealed rupture of the carpal sheath. Prognosis is not known.

Fractures of the proximal aspect of the splint bones can lead to OA of the carpometacarpal joint. Fracture of the medial splint bone is most serious, but polo ponies usually respond well to conservative management.

Horizontal and vertical fracture of the accessory carpal bone may occur after collapse or a fall. Ponies are occasionally hit on the forehead by a hard-struck polo ball, rendering them unconscious and causing the hind hoof to hit the back of the carpal region. Fracture can also occur if a horse trips inadvertently on a loose polo wrap. Prognosis appears to be indirectly proportional to fracture displacement. Treatment is conservative. Physiotherapy, forcing full carpal flexion, is helpful to restore normal mobility (SK). Tenosynovitis of the carpal sheath can occur primarily or after fracture of the accessory carpal bone and in ponies with tendonitis of the SDFT and DDFT, as well as in horses with desmitis of the accessory ligament of the SDFT, but this condition is rare.

Fig. 119-14 • Transverse ultrasonographic image of the distal palmar metacarpal region. An acute injury caused by direct trauma resulted in a chronically thickened palmar annular ligament and huge anechogenic areas within it. PAL, Palmar annular ligament; SDFT, superficial digital flexor tendon; DDFT, deep digital flexor tendon.

Desmitis of the Accessory Ligament of the Superficial Digital Flexor Tendon

In the United Kingdom, between 10 and 15 polo ponies each year are diagnosed with desmitis of the accessory ligament of the SDFT, which may occur because of the fast and aggressive play of modern polo (PJM). Awareness of the condition and use of ultrasonography may have resulted in increased recognition.

One high-goal player had five horses with this problem in a single year. Diagnosis is made by eliminating the distal aspect of the limb as a source of pain, by palpating pain and swelling in the distal aspect of the antebrachium and in the carpal sheath, and by ultrasonographic assessment. Conservative management is usually successful, including the periligamentous injection of hyaluronan and corticosteroids. Surgical resection of the accessory ligament of the SDFT may be indicated, particularly in polo ponies with considerable fibrosis and bony proliferation on the caudal distal aspect of the radius or in those that stand over at the knee.

Upper Forelimb Lameness

Lameness associated with the antebrachium, elbow, and shoulder regions is uncommon in polo ponies. Occasionally, fractures of the radius or olecranon and wounds with bony sequestration occur from kick trauma. Repair of fractures of the olecranon has been successful. Shoulder region soft tissue trauma, fracture of the supraglenoid tubercle of the scapula, and suprascapular nerve injury occur occasionally from falls, dangerous play, or wrecks.

Other Hindlimb Lameness

The distal aspect of the hindlimb is subject to the same type of bony injuries as seen in the forelimb, with the exception of navicular disease. Fractures of the distal and proximal phalanges and PSBs occur with the same frequency as in the forelimb, but prognosis is better in the hindlimb. In the hindlimb, OA of the fetlock joint, SDF tendonitis, suspensory desmitis, and desmitis of the ALDDFT are not nearly as common as in the forelimb.

Two soft tissue problems occur specifically in the hindlimbs. A form of severe suspensory desmitis occurs in older polo ponies with exceedingly straight hock conformation. The hind fetlock joint drops, and the pastern region is parallel to the ground. However, lameness is often minimal, and despite the abnormal angle of the fetlock joint, these horses can continue to play for years with the help of support wraps. The second specific soft tissue injury of the hindlimb is spontaneous rupture of the common digital extensor tendon above the fetlock joint. This injury results in lameness and hyperflexion of the fetlock joint at the trot. These horses respond well to conservative management, with support wraps and rest, and prognosis is excellent.

Lameness from stifle injuries is uncommon. Osteochondrosis occasionally causes effusion and lameness or poor performance if present bilaterally. Collateral ligament injury may occur from severe bumps. Kick wounds to the tibial crest can cause pronounced lameness and may result

in a fracture. Polo ponies with a history of poor stopping or turning ability respond favorably to injection of counterirritants (blisters) around the patellar ligaments and the insertion of the vastus lateralis and rectus femoris muscles. Horses are kept in a working schedule following these injections and typically may be played successfully several days later.

Pelvic injury in polo ponies is infrequent but may result from dangerous play, such as a high-angle ride off behind the saddle (SK), and is best diagnosed using scintigraphy. Stress fractures of the ilium and traumatic fracture of the acetabulum occur but are rare. Disparity in height of the tubera sacrale often is seen, but with no effect on performance.

Rhabdomyolysis

Rhabdomyolysis, or tying up, is fairly common, especially in mares. Two types of horses are predisposed to this syndrome. Unfit horses placed into work too rapidly often develop a stiff gait at the trot and tenderness to palpation over the dorsal musculature. Muscle enzyme levels are only moderately elevated, and horses respond well to rest and NSAIDs. The most common form of rhabdomyolysis is seen in fit polo mares after an extended layup period for illness, unrelated lameness, or foul weather that prevents horses from being played regularly. Rhabdomyolysis can also occur on cold, clear mornings or blustery days during which a decrease in barometric pressure occurs. Horses generally become affected after exercise (when they return to the barn or trailer), are reluctant to move, and have firm, tight gluteal regions. Epaxial muscles rarely are involved. Clinical signs may be confused with colic because horses with rhabdomyolysis often paw, stretch out, and sweat profusely. Muscle enzyme levels are elevated greatly. Management is similar to that described for other sports horses (see Chapter 83). Nutritional management appears to be important in Europe, where bran, which is high in phosphorus (reduces calcium), is fed to reduce recurrence.

Gracilis Muscle Tear

Gracilis muscle tears are seen in several polo ponies each year and are characterized by lameness at the trot and dramatic swelling in the medial thigh region. Abduction of the flexed hindlimb elicits a painful response, and a large hematoma generally develops soon after the injury. The administration of NSAIDs and DMSO intravenously, and the topical application of cold water are beneficial. If necessary, seroma fluid can be drained surgically 5 to 7 days after injury, and exercise is limited for a minimum of 2 weeks.

Equine Protozoal Myelitis

Mild neurological signs typical of equine protozoal myelitis (EPM) or lameness associated with the disease can be confused with other causes of musculoskeletal pain, in particular hindlimb lameness. EPM is prevalent in the United States but is rare in England (PJM). Occasionally, a polo pony in the United Kingdom that was imported from the United States develops clinical signs consistent with EPM under the stress of the latter half of the season.

Chapter 120

The Western Performance Horse

THE CUTTING HORSE

Jerry B. Black and Robin M. Dabareiner

DESCRIPTION AND HISTORY OF THE SPORT

The cutting horse was born of necessity long ago on the open grass plains of West Texas. This was the era of Western history that included big cattle drives from the open ranges of ranches such as Burnett and the 6666 Ranch, Waggoner Ranch, the Pitchfork Ranch, and the Matador Ranch to Dodge City, Kansas. Cutting horses enabled big country ranches, where no barbed-wire fences existed, the only means of working vast herds of cattle. In those days the task of the horse was simple, at least by definition. Guided by the rider, the cutting horse entered a herd of cattle quietly and deliberately. A single cow was cut, or separated, from the herd. The natural instinct of the cow is to return to the safety of the rest of the herd. The cutting horse, through breeding and training, controlled the cow with a series of moves and countermoves. The speed, agility, balance, and quickness of the cutting horse kept the cow from the herd, where other cowboys would hold the cut. The horse and rider would reenter the herd again and again, cutting cattle out until the work was done. Only the top hands earned the right to ride the best horses of the remuda (herd), the cutting horses.

The unique skills of the cutting horse were a great source of pride to the frontier cowboy. This often led to impromptu or jackpot cuttings on the open range or, from about 1900, in outdoor pens of the large ranches. From this love of the cutting horse, as well as the subsequent competition to determine who had the best horse, came the roots of cutting as we know it today. The first cutting horse contest for money was held at the 1898 Cowboy Reunion in Haskell, Texas. Twelve cutting horses competed for a purse of \$150. From this start, regular events occurred on ranches of the Southwest and at the Fort Worth Stockyards. Rules and prizes varied greatly, but the ability of the cutting horse to separate a single cow from the herd always was and continues to be the goal of the competition. From these roots the National Cutting Horse Association was formed in 1946 during the Fort Worth Exposition and Fat Stock Show. The stated purpose of the organization was to standardize the rules and judging of competition and to preserve the tradition and history of the cutting horse with the ranching and livestock industry.

Today competitions approved by the National Cutting Horse Association occur throughout the United States and Canada. In addition, many association members from other countries, such as Australia, are conducting competitions outside North America. The format of these competitions

and other Western performance horse disciplines, such as reining, presents a unique challenge to the equine veterinarian.

TRAINING

Training of the cutting horse begins at 2 years of age. Usually 60 to 90 days are spent in basic training before the horse is introduced to cattle. This generally is accomplished by turning one cow into a round pen that is 38 to 54 m in diameter. The horse is taught to mirror the movements of the cow as the cow moves around the perimeter of the arena. This process of training a cutting horse is repetitive and is done several days a week for months. The object of training is for the horse to develop an ability to perform identical movements with the cow. Simply put, when the cow stops or stops and turns, the horse does the same maneuver. This type of training is accomplished by asking the horse to stop with the aid of a bridle and turning the horse to move with the cow. The key to training is a complete and balanced stop. With time, a stop ultimately is followed by the instinctive ability of the horse to “read” the movement of the cow and to turn in the direction the cow is going. Because this ability to watch a cow and respond to its movement is instinctive to the working stock horse, breeding is of the utmost importance. Without this genetic instinct a horse simply does not respond to the movement of a cow and does not initiate a stop or turn as necessary to continue to track the cow. A good cutting horse trainer knows in a relatively short period if a young horse has the instinct and athletic ability to be a successful cutting horse. A finished cutting horse must perform the necessary moves to keep a cow in proper position away from the herd, without any hand cues from the rider, relying on instinct alone to read the movement of the cow. Reining the horse is permitted only to make the cut of a single cow out of the herd. After the cut is successfully made, the reins are placed in a relaxed position on the horse's neck, and only leg cues are permitted from the rider during the actual working time. The ability of a horse to contain an individual cow provides the excitement of competition in cutting.

Training of a cutting horse prospect that has shown good potential continues when it is a 3-year-old, preparing it for the first major competitions, the futurities. The futurity is the first of the horse's aged event competitions that continue for 4 years. No horse can compete in aged events beyond 6 years of age. Aged events consist of two elimination go-rounds, followed by the semifinal and the final competition. Substantial musculoskeletal stress is placed on these athletic performance horses, with multiday competitions over a short period. In addition, the horses usually are practiced with cattle daily, including the day of competition, to sharpen performance skills. Competition in these aged events is heavy, with the major shows having more than 500 entries in a single age division. Purses in this type of event can exceed a total of \$1 million. The nature of this aged event competition, with large purses in numerous events over a 4-year period, has caused the cutting horse economy to grow rapidly during the past several years. Select yearling and training sales are conducted annually

that are beginning to parallel the racing industry in financial return on sales. This has contributed to the current popularity and resurgence of breeding of cutting and Western stock horses, which in turn will ensure the preservation of the tradition and heritage that this horse played in the history of the great Old West.

LAMENESS EXAMINATION

The increasing popularity of the cutting and reining horse for show and performance is occurring nationally and internationally. Sales of this type of horse have increased to Europe, South America, and other countries. In North America, the revival of interest stems primarily from excellent programs instituted by associations such as the National Cutting Horse Association and the National Reining Horse Association. These associations encourage owner participation at an amateur level in cutting and reining events. This type of performance horse creates a new diagnostic and treatment challenge for attending veterinarians, partially because of the rigid training schedules necessary for 3- to 6-year-old horses to compete in futurities and aged events.

Hindlimb lameness presents one of the more interesting diagnostic challenges to an equine clinician. The lameness is often difficult to diagnose and even more difficult to manage. A systematic approach must be developed to achieve an accurate diagnosis consistently. The veterinarian must use a routine that is repeated with each horse and must allow sufficient time to complete a thorough examination. Western stock horses may be difficult to evaluate while being led. These horses usually are not taught to lunge and are often difficult to trot in hand. A 10- to 15-m round pen with firm footing has proved to be beneficial for evaluating lameness.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC LAMENESS

Hindlimb lameness is more common than forelimb lameness in cutting horses. Mixed lameness with swinging and supporting components is common in hindlimbs, especially in upper limb lamenesses such as those involving the hock, stifle, and hip or sacroiliac region. Hindlimb lameness may be associated with two sources of pain: for example, chronic hock lameness and secondary lumbar and gluteal myositis. This section focuses on selected hindlimb lamenesses of the hock, stifle, and thoracolumbar regions.

Selected Lameness of the Tarsus

Osteoarthritis of the Distal Tarsal Joints (Distal Hock Joint Pain)

Osteoarthritis (OA) of the distal tarsal joints is seen most commonly in horses that have repeated, excessive compression and rotation of the hocks at high speed, and a high incidence occurs in young working cow horses and in cutting and reining futurity prospects, reflecting the demanding training schedules of 5 to 6 days a week at 2 and 3 years of age. Sickie hocks, cow hocks, and narrow hocks also may predispose horses to lameness. OA also may develop secondary to partial collapse of the central and third tarsal bones, and affected horses often develop

lameness within the first year after birth. In one author's practice (JBB), routine survey radiology of the tarsus in 20, 2-year-old cutting horse prospects before training began revealed evidence of OA in 11 (55%).

Clinical signs include reduced height of the foot flight arc, resulting in abnormal toe wear, and a shortened cranial phase of stride. Hard work increases the degree of lameness, although most horses are lame and stiff when first taken out of the box stall and improve to some degree during the initial warm-up. Trotting in a circle increases the degree of lameness. Gait alteration or lameness may be observed with the affected limb on the inside or outside of a circle. Cutting, reining, and stock horses are reluctant to stop properly. Upper limb flexion often increases the degree of lameness. Palpation of the distal medial aspect of the hock may reveal an exostosis and soft tissue thickening. Deep palpation of the area can cause a painful withdrawal response. Thoracolumbar pain is present in about 50% of horses.

Diagnosis is based on a positive response to intraarticular analgesia and radiology. Radiological abnormalities are often only seen in a dorsolateral-plantaromedial image in 2- to 4-year-old cutting horses, findings that differ from those seen in other young sports horses.

Therapy varies depending on the degree of lameness. Rest is generally not helpful in horses with advanced OA, and obtaining trainer compliance if the lameness is subtle is difficult. Training usually is continued with the help of nonsteroidal antiinflammatory drugs (NSAIDs), such as phenylbutazone (2 g daily or 1.5 g twice daily) and intraarticularly administered antiinflammatory drugs. Shoeing changes include removing excessive toe, squaring the toe of the shoe, and extending both branches of the shoe for more heel support. Half-round shoes help aid breakover in some horses with cow-hocked or sickle-hocked conformation. Changes in training schedules include more paddock or free-choice exercise and longer warm-up periods before training. Training in deep surfaces, overtraining, or conditioning in circles should be avoided. Varying the gait frequently during training and conditioning helps the horse to stay more comfortable.

Intraarticular medication is used to keep chronically lame horses in competition. A combination of methylprednisolone acetate (40 mg) and hyaluronan (10 to 20 mg) is injected separately into the centrodistal (distal intertarsal) and tarsometatarsal joints in horses with advanced OA. The veterinarian should not rely on communication between the two joints. If good results are achieved, these injections are repeated as necessary every 12 to 16 weeks. Horses with early OA respond favorably to intraarticular treatment with hyaluronan (20 mg of Hylartin-V, Pfizer Inc., New York, New York, United States) and triamcinolone acetonide (3 to 6 mg). Intravenous injections of hyaluronan (Legend [Bayer HealthCare LLC, Animal Health Division, Shawnee Mission, Kansas, United States]; 40 mg in 7-day intervals, series of three) or intramuscular injections of polysulfated glycosaminoglycan (PSGAG; 500 mg of Adequan [Luitpold Animal Health, Shirley, New York, United States] intramuscularly [IM] in 5-day intervals, series of four to eight) are used frequently as concurrent therapy. Combinations of intermediate-acting corticosteroids and hyaluronan administered intraarticularly have been used in horses that are lame immediately before leaving for circuit shows or

important multiday competitions, such as cutting horse, snaffle bit, and reining horse futurities.

Therapeutic levels of NSAIDs may be necessary during competition if allowed by the breed, performance, or state drug regulations governing the event. Phenylbutazone (2 g daily or 1.5 g twice daily) is usually effective. However, many stock horse trainers believe that this drug tends to dull the mouth and sides of the horse, thus limiting bit and spur response. Other NSAIDs that are effective include flunixin meglumine (Banamine [Intervet/Schering-Plough Animal Health, Roseland, New Jersey, United States]; 1 mg/kg daily) or ketoprofen (Ketofen [Pfizer Inc.]; 2 mg/kg daily). Horses vary in response to the therapeutic effects of each NSAID. If one drug is not effective, a different one should be assessed. Tiludronate and interleukin-1 receptor antagonist protein (IRAP) have recently been introduced, but long-term follow-up results are not known. Tiludronate is administered as a single intravenous infusion. IRAP is injected three to five times at 1- to 2-week intervals. Focused extracorporeal shock wave therapy is used in horses refractory to intraarticular medication.

Surgery has been an important adjunct to OA therapy in horses requiring repeated intraarticular injections or continual therapy with NSAIDs. Horses with mild to moderate radiological changes but normal joint spaces respond favorably to cunean tenectomy. Horses with substantial intraarticular changes and joint space collapse are treated best surgically with a combination of cunean tenectomy and arthrodesis (fenestration) of the affected joint or joints using a 3.2-mm drill bit and creating three to four tracts. The horse is returned to work as soon as possible after surgery to encourage ankylosis. Handwalking is begun the day after surgery, and light riding at a walk may begin 2 to 3 weeks later. Light riding exercise continues for another 3 weeks, and full training begins 45 to 60 days postoperatively if the horse is reasonably comfortable. Phenylbutazone, 2 g once daily as needed, is used initially if obvious lameness persists. Most horses show almost immediate improvement after surgery. This improvement may be caused partially by the release of intraosseous pressure after the fenestration procedure, plus cessation of the rotational effect of the cunean tendon on the distal aspect of the tarsus. Radiological evidence of ankylosis occurs over a prolonged period, even up to 1 year postsurgery. Soundness does not seem to be related to radiological evidence of ankylosis.

Prognosis varies depending on the degree of OA, the number of joints involved, and the type of competition in which the horse is engaged. Surgery offers the best prognosis for horses with chronic lameness. It is possible that chemical fusion with ethyl alcohol may offer a shorter convalescent time.

Arthrosis of the Tarsocrural Joint

Distention of the tarsocrural joint capsule is usually the result of osteochondrosis or trauma. Osteochondrosis lesions occur on the cranial aspect of the intermediate ridge of the tibia, the trochlear ridges of the talus, and the lateral or medial malleoli of the tibia. Trauma is related to quick turns, hard stops, loss of balance, and poor footing. Faulty conformation, such as overly straight angulation of hock and stifle joints, may be a predisposing factor.

Distention of the tarsocrural joint capsule is observed most easily on the dorsomedial aspect of the hock, but swelling also occurs in the plantar pouches, laterally or medially. The horse may have pain on palpation. A proximal limb (hock) flexion test may or may not be positive, depending on the degree of joint capsule distention and synovitis. Radiographic examination is essential to determine the cause and should be repeated after 10 to 14 days if initial radiographs are normal.

Horses with osteochondrosis are treated surgically. Horses with traumatic distention of the tarsocrural joint are treated by intraarticular injection of intermediate-acting corticosteroids and hyaluronan, two or three times, 14 to 21 days apart. Intraarticular injections often are followed by hyaluronan (40 mg) administered intravenously weekly for 3 weeks. All injected hocks are bandaged concurrently to help reduce joint effusion. Pressage elastic contour bandages (Jupiter Veterinary Products, Harrisburg, Pennsylvania, United States) provide adequate pressure and are easy to maintain. The horse is given rest for 3 to 6 weeks.

Exploratory or diagnostic arthroscopy is justified in any horse that does not respond to conservative therapy, permitting identification of subtle osteochondrosis lesions not detectable radiologically and soft tissue injuries, as well as providing joint lavage.

The prognosis is good if treatment is initiated early and if all fragments and debris are removed soon after the synovitis is recognized in horses with osteochondrosis lesions or severe trauma. If conformation is the predisposing cause, the prognosis is poor.

Selected Lameness of the Stifle

The stifle is a large, complex joint composed of two articulations: the femorotibial and femoropatellar joints. One author's experience (JBB) has been that during arthroscopy of the femorotibial joint, despite high intraarticular fluid pressure, obvious distention of the femoropatellar joint capsule does not occur. Thus little or no distention of the femoropatellar joint capsule occurs in association with disease of the femorotibial joint. When performing intraarticular analgesia of the stifle, all three compartments should be injected separately.

Osteochondrosis

Osteochondrosis of the trochlear ridges of the femur is seen commonly in young horses. Clinical signs include distention of the femoropatellar joint capsule and varying degrees of lameness, depending on the amount of joint surface involved. Diagnosis is confirmed radiologically. Arthroscopic surgery is the treatment of choice to debride all diseased cartilage and bone and to remove all free-floating bone and cartilage. Aftercare consists of 45 to 60 days of stall rest, followed by an equal amount of stall and paddock confinement. Training generally resumes 3 to 6 months postoperatively. Intraarticularly administered hyaluronan (20 mg) followed by intramuscularly administered PSGAGs (500 mg in 5-day intervals, series of four to eight) 2 to 3 weeks after surgery has helped to reduce postoperative synovitis.

Subchondral Bone Cysts

Subchondral bone cysts of the medial condyle of the femur are the most frequently recognized bony lesions of the stifle

in one author's (JBB) practice. Affected horses are lame at the walk or trot in one or both hindlimbs. The degree of lameness varies greatly among horses. Some horses are subtly lame, requiring riding or repeated flexion to produce a recognizable lameness. Others have acute, severe lameness and are unwilling to trot. Moderately lame horses tend to swing the toe medially during protraction. This contrasts with horses with painful conditions of the femoropatellar joint or patellar ligaments, with which the horse often carries the stifle out or abducts the limb. Lameness may be more obvious with the affected limb on the inside of a circle.

Subtle distention of the femorotibial joint capsule may be palpated between the medial patellar and medial collateral ligaments. Some horses resent deep digital pressure over the medial femoral condylar region.

Diagnosis of subchondral bone cysts is based on clinical signs and response to intraarticular analgesia using 30 mL of mepivacaine and radiology. Conservative treatment for the most part yields only temporary improvement in the lameness and is used only when a performance horse needs to compete for the remainder of the season or when finances prohibit surgical intervention. Conservative treatment consists of intraarticular injections of hyaluronan, with or without corticosteroids such as betamethasone or triamcinolone acetonide. Intramuscularly administered PSGAGs, given in a series of four to eight injections at 5-day intervals, are also used. Many trainers report a pronounced effect about 24 hours after administration of PSGAGs. Therapeutic levels of systemic NSAIDs may be also necessary during multiday competitions. Owners should be informed that continued training and competition over an extended period might lead to secondary OA.

There are several treatment options, but the treatment of choice in our experience is curettage and fenestration of the subchondral bone cyst. Before 1988, this procedure was done through an arthrotomy incision. Although the surgery was successful in most horses, wound dehiscence and prolonged hospitalization were of great concern. Currently the surgery is performed by arthroscopy, with the horse placed in dorsal recumbency and the limb in flexion. This position provides adequate visibility and good access to the cystic lesion via an instrument portal. Postoperative hospitalization is minimal, and to date no postoperative complications have been seen. The horse is confined for 60 days after surgery. Handwalking for 10 minutes daily is allowed during confinement. Free-choice exercise for an additional 2 to 4 months is allowed. Training usually resumes 6 months postoperatively or earlier, if the horse is sound. Surgical success is about 50% to 60%. Most of these horses return to a competitive level of performance, if given adequate rest. Recently arthroscopic injection of corticosteroids into the fibrous tissue of subchondral cystic lesions has been described.¹ A retrospective study examined 52 horses with subchondral cystic lesions in the medial femoral condyle that were injected with arthroscopic guidance with a reported success rate of 77%. Preexisting osteophytes had a negative impact on outcome. This seems like a viable first option for treatment, and if unsuccessful then surgical debridement and fenestration can be performed.

Upward Fixation of the Patella

Partial or complete upward fixation of the patella is a common cause of stifle pain, which can eventually produce

articular changes of the patella. Upward fixation of the patella can occur in any type of body conformation and hindlimb angulation and may be related to the anatomical formation and depth of the notch on the proximal aspect of the medial trochlea of the distal aspect of the femur. Lack of condition and loss of condition are contributory factors. Poor coordination between extensor and flexor groups of the stifle and lack of quadriceps development may explain why upward fixation is seen in young horses at the beginning of training. One of us (JBB) examined two horses in which upward fixation of the patella was secondary to a subchondral bone cyst in the medial femoral condyle. Upward fixation may have been caused by alteration of gait and foot placement because of pain in the medial femorotibial joint. Upward fixation resolved after arthroscopic treatment of the subchondral bone cyst. The duration of locking varies from an almost instantaneous release, with only slight backward jerk evident, to a complete locking that can last for hours and may require surgical release.

Diagnosis is based on clinical signs. Often, although no obvious upward fixation occurs in extension, the limb snaps with an audible click while in an extended position. Occasionally, pushing the patella over the top of the trochlear ridge when the limb is in extension can produce the locking. Clinical signs often are exacerbated if the horse is walked down a steep slope. The diagnosis is sometimes based almost entirely on the owner's or trainer's description of the condition.

Treatment should remain conservative when possible. If complete upward fixation has occurred for any period, the femoropatellar joint usually has effusion. Treatment should be aimed initially toward reducing inflammation and resting the tissues involved. The usual treatment schedule includes administration of systemic corticosteroids (20 mg of dexamethasone [Azium, Intervet/Schering-Plough Animal Health] IM daily) for 1 to 3 days, followed by 3 to 5 days of NSAIDs (2 g of phenylbutazone twice daily). Handwalking for 5 to 10 minutes is allowed if no further upward fixation occurs, but no free-choice exercise is allowed. Excessive toe is removed, and wedged shoes or wedge pad and flat shoes are used if the heel is low. Half-round shoes allow the horse to break over in its most comfortable and natural position.

Once the initial inflammation has subsided, a conditioning program is started. Long warm-up periods are essential. Thirty minutes of walking and trotting, followed by an increasing amount of extended trotting on the straightaway are recommended. Once the horse becomes conditioned, trotting in the hills is prescribed, where possible. The concept of conditioning is to improve quadriceps development and tone and to improve overall coordination. Horses that are underweight should be fed to gain weight and to improve the overall body condition and the condition of the muscles involved in movement of the stifle.

Horses that do not respond to conservative treatment may require an internal blister, medial patellar desmotomy, or medial patellar desmoplasty. Internal blister is accomplished by local infiltration of 2% iodine in peanut or almond oil injected directly into the body of the medial patellar ligament. Care must be taken to avoid the accidental penetration and injection of the femoropatellar joint

with the counterirritant solution. If this is unsuccessful, splitting the medial patellar ligament is a viable option. This can be performed in either a standing sedated horse or under intravenous anesthesia. The area over the medial patellar ligament is clipped and scrubbed, and a number 15-scalpel blade or 14-gauge needle is inserted at 1-cm intervals and used to scarify the ligament perpendicular to the longitudinal axis of the limb. The thought is that by creating inflammation and scar tissue, the ligament will tighten, thereby preventing upward fixation of the patella. This treatment has been very successful in one of our hands (RMD). Medial patellar desmotomy should be reserved as a last form of therapy because the postoperative complications include fragmentation of the distal aspect of the patella, soft tissue fibrosis, and mechanical alteration of gait.

Femorotibial Joint Pain

Subtle soft tissue injuries may occur in the femorotibial joint, resulting in low-grade lameness that is most evident when the horse trots in circles. Such injuries often occur as training is increased. A typical example is a young cutting horse that is being worked hard on cattle before a futurity. The horse has a shortened cranial phase of stride and lowered foot flight, causing toe drag. Results of hindlimb flexion tests are generally negative. Mild distention of the medial femorotibial joint capsule may be palpable. Diagnosis is based on clinical signs, response to intraarticular analgesia of the femorotibial joint, and the absence of radiological abnormalities.

Treatment comprises intraarticular medication with hyaluronan and corticosteroids such as triamcinolone acetonide (6 mg), plus intramuscularly administered PSGAGs. Systemic NSAIDs are given in decreasing doses over 10 to 14 days. All trailers and calks are removed from shoes. A wedge pad may be added with an egg bar shoe or extended branch shoe, depending on the amount of heel support needed.

Training is resumed after 14 to 21 days of rest. Long warm-up periods and extended straightaway trotting are recommended to condition the muscles of the upper hindlimb.

Prognosis is good if a consistent training schedule is maintained. Horses with irregular training schedules and frequent periods of several days off between exercise sessions tend to have recurrent problems.

Thoracolumbar Injuries

Thoracolumbar Myositis

Soft tissue injuries of the thoracolumbar region produce back soreness and are common injuries in a working stock horse. Thoracolumbar myositis may coexist with hindlimb lameness, such as distal hock OA, or may be a primary traumatic lesion, frequently caused by the extraordinary forces of rotation and propulsion placed on the hindlimbs. Other factors include rigid training and competition schedules such as the fall futurities for 3-year-olds that result in an overworked young horse.

Local myositis involving the muscles of the thoracolumbar and pelvic region can have a profound effect on the performance of a stock horse. A cutting horse has three basic components to work: the stop, turn, and ability to

track a cow in mirror image across the arena at high speed. Localized back pain results in decreased performance in all of these, without obvious lameness. The trainer perceives that the horse is simply not trying. Consequently, a horse with back pain is forced to try even harder and soon falls into the overworked category.

Clinical signs of thoracolumbar myositis include pain to palpation of the affected muscle groups and associated spinous processes, obvious discomfort during saddling or mounting, subtle bilateral or unilateral hindlimb lameness, unwillingness to stop in form, and overall lack of performance. Flexion tests are seldom positive, unless the back problem coexists with distal hock joint pain. One may reasonably believe that arthrosis of vertebral articulations in the lumbar and lumbosacral region exists in some horses. However, because of the depth and mass of the muscles involved, distinguishing the exact pathological condition or even the exact site of the injury is impossible.

Therapy is aimed at reducing inflammation and controlling the associated muscle pain and spasms. Prolonged rest periods from training always are indicated but in reality are difficult to achieve because of the rigid schedule of preparation for competition. For example, an average futurity horse being prepared for the National Cutting Horse Association futurity in December of its 3-year-old year accumulates a \$20,000 to \$24,000 debt in training and entry fees alone before competition. Convincing an owner and trainer that a horse should be allowed to rest immediately before the futurity is difficult, if appropriate therapy has even a remote chance of being effective.

The systemic use of skeletal muscle relaxants such as methocarbamol (10 mg/kg orally [PO] twice daily for 5 to 10 days) has been effective in treating cutting horses with generalized back pain. Dexamethasone (10 mg PO twice daily for 3 to 4 days) is indicated in horses with acute pain. Horses with chronic back pain may be treated successfully during competition with a single dose of triamcinolone acetonide (12 to 16 mg IM) and methocarbamol administered orally. NSAIDs generally have not been effective unless the back pain is secondary or coexists with distal hock joint pain. Care must be taken to comply with any medication rules.

Specific localized pain may be treated successfully by local injection of methylprednisolone acetate (200 to 400 mg) and Sarapin (50 mL; High Chemical Company, Levittown, Pennsylvania, United States). Treatment is repeated every 10 to 14 days until pain subsides.

Other management considerations are important for recovery. Horses with low, underslung heels of the hind feet should be shod using raised heels. Evaluation of the fit of the saddle, type of pad, and specific pressure points when ridden should be considered. Other modalities of therapy, such as pulsed electromagnetic field and therapeutic ultrasound, have been useful in keeping a horse in competition. Long warm-up periods without the rider for 30 to 45 minutes by ponying (leading from another horse) at a walk and trot always are indicated. The trainer must be cautioned that overwork and severe fatigue must be avoided at all times.

Sacroiliac Region Pain

Strain and subluxation of the sacroiliac joint are not uncommon in working stock horses because of twisting

and rotation of the back and pelvis during work. This rotation is complicated by the weight of tack and the rider, who is attempting to maintain balance and remain stationary on top of the horse during sudden hard stops, turns, and bursts of speed.

Many of the clinical signs observed in horses with thoracolumbar myositis are also common in those with sacroiliac region pain because the epaxial muscles go into spasm to provide stability to the traumatized sacroiliac joint. However, bilateral or unilateral lameness with stiffness and alteration of gait usually are associated with sacroiliac region pain. Protrusion of the tubera sacrale may be evident when the horse is walking away from the observer. Flexion of the contralateral limb for 2 minutes may result in elevation of the tuber sacrale, hip hike, and stiffness of the affected limb. Digital palpation adjacent to the tuber sacrale and over the gluteal regions usually elicits pain. Local infiltration of local anesthetic solution may result in improvement, but rarely are clinical signs fully alleviated.

Deep intramuscular injections of methylprednisolone acetate (400 mg) and Sarapin (50 mL) into the region of the sacroiliac joint have been effective in treatment. Disposable needles at least 10 cm long are necessary to reach the affected area. Strict aseptic technique must be followed. Injections usually are repeated after 2 to 3 weeks. Concurrent systemic therapy with NSAIDs is beneficial. Horses must have rest, and 2 to 6 months out of training is often necessary, with strict stall confinement for the first 30 to 45 days.

Proper therapy and management of injuries to the thoracolumbar and sacroiliac regions generally are rewarding if initiated early in the course of the disease. Horses with chronic recurrent problems usually can be managed to allow some level of competition.

Forelimb Lameness in the Cutting Horse

Forelimb lameness in the cutting horse is similar to that described in the roping horse (see the following section).

■ THE ROPING HORSE

Robin M. Dabareiner

TEAM ROPING HORSE

Description of the Sport

A unique handicapping system implemented in the early 1990s has contributed to team roping becoming a rapidly growing equestrian sport. Team roping began as a rodeo event many years ago, evolving from the everyday work of cowboys on ranches. If a cow needed to be treated on the open range, the only method of restraint was to secure the head and heel of the animal, or to team rope it. The cowboys soon began wagering among themselves to see which team of a header and heeler could accomplish this feat in the shortest time. Currently nearly 1 million people compete in team roping competitions in North America.

Because of the large number of participants, team roping has become of great economic importance. Many team roping organizations exist nationally, but the most prestigious is the United States Team Roping Championships. The numbering or handicapping system of the team ropers was begun by the United States Team Roping

Championships and has become standard. A number, from 1 to 9, with 9 being the highest level of ability, is assigned to each of the team ropers. This number is based on various factors, including ability, previous prize earnings, experience, age, and physical handicaps.

The roping categories also are assigned a numerical value that cannot be exceeded by the total handicap numbers of the two participating ropers. The highest level of roping is the open roping, which is open to any roper but usually is entered by professional ropers (numbered 9), allowing the world champions to compete together. The lowest number is a true beginner, who would be a number 1 or 2. This handicap system allows the lower-level ropers to compete as a team with the world champions and to level the playing field of competition at all levels. The entry fees of the participants usually generate the purse money in a jackpot fashion. A portion of the entry fee is held out by the producer of the roping to pay for the arena, the cattle, and advertising, and the rest of the fee is placed in the purse money to be divided among the winners.

Dally team roping is a timed event involving five basic elements: the header, the heading horse, the heeler, the heeling horse, and the steer. The steers that are used for the team roping event are usually horned cattle called Corriente cattle, often from Mexico. Other types of cattle used are longhorns or other native homed breeds ranging in weight from 170 to 320 kg.

A typical run in dally team roping begins with a steer contained in a chute at the end of an arena. The heading box is to the left of the chute, and the heeling box is to the right of the chute. When the header calls for the steer, or asks that the steer be released from the chute, the chute gate is opened and the steer is allowed a head start called the score. If the header leaves the heading box before the steer crosses the score line, or reaches the predetermined head start, then the team is issued a penalty of 10 seconds. The timing of the run is begun when the steer crosses the score line.

When cued by the riders, the horses leave the roping box much as a racehorse leaves the starting gate to attain maximum speed as quickly as possible. As the header approaches the steer with the heading horse running at full speed, the horse is trained to rate off, or to slow up slightly, once the horse reaches the hip of the steer, to position the steer properly so that the header may rope the steer. Team roping has three legal head catches: both horns (a clean horn catch), a half head (one horn and the nose of the steer), or a neck. All other catches are considered illegal, and the team is given a no time.

After the header successfully catches the head of the steer and dallies (wraps in a full circle) the rope around the saddle horn, the heading horse drops its hindquarters and slows somewhat as it sets the steer and brings the steer's head around to the left. As the steer's body progresses to the left, the heading horse also is turned to the left and is moved out in front of the steer to allow the header to pull it across the arena at about a 90-degree angle to the original direction of travel, maintaining a constant slower speed, thus allowing the heeler to get into position to rope the hindlegs of the steer.

As the header sets and turns the steer, the heeler turns left following the steer and positions just behind and slightly to the left of the steer as it is taken across the arena.

As the heeling horse follows the steer in this position, maintaining a constant speed equal to that of the header and steer, the heeler properly times his swing and then releases the heel rope, placing the loop under the steer and ropes the hindlegs of the steer. If only one hindleg is caught, then the team is issued a 5-second penalty. As the slack is taken out of the heel loop and as the dally is made on the saddle horn, the heeling horse is signaled to drop its hindquarters and come to an abrupt stop.

As the heading horse progresses away from the heeler with the steer still in tow, the ropes come tight, and when tight, the heading horse is cued to spin around to the right while maintaining a tight rope to face the steer. When the facing is complete, the rope is tight and in a straight line from the saddle horn of the header to the head of the steer and is tight from the hind feet of the steer to the saddle horn of the heeler, and then the flagman signals the end of the run and the time is taken.

The roping can be accomplished by experts in 6 to 7 seconds but requires thousands of hours of practice to achieve this and to minimize the danger to all the participants. Runs recorded in the range of 3.4 to 3.6 seconds have been made by the World Champion-caliber team ropers.

Conformation

The horses, predominately geldings, used in team roping are usually American Quarter Horses (QHs), preferred because of exceptional athletic ability, quick acceleration over short distances, and a good mind. Other breeds are rarely used. The head horse must be larger and faster than the heel horse. Head horses typically weigh 545 to 590 kg and are heavily muscled to tow the steer across the arena. The heel horse is smaller and quicker with more cow sense than the head horse. Horses that are trained for cutting but no longer are competing often make good heel horses because of size and cow sense. Team ropers prefer a mature,

experienced horse, and so horses are usually over the age of 10 years, and many top ropers have horses in the mid to late teens. Therefore repetitive injuries are common, but because horses often have had several owners, a complete medical history is rarely available. In a recent retrospective study looking at lameness and poor performance in horses used solely for team roping, horses used for heading were significantly heavier (median weight, 545 kg; range, 473 to 603 kg) and older (median age, 12 years) than heeling horses (median weight, 490 kg; range, 441 to 545 kg; median age, 9.5 years).¹

Training

The training of heading and heeling horses involves thousands of team roping runs and many thousands of miles of hauling. The horse must anticipate every variable of a team roping run, so that rider intervention is unnecessary. This allows the roper to focus on nothing but the speed of the run, which is an important factor contributing to injury. The current high demand for a finished team roping horse has greatly increased the value of these horses, and because replacement is difficult, veterinary advice is now sought more often.

Historical Data and Decreased Performance

It is imperative for a clinician to know whether a team roping horse is used primarily as a heading or heeling horse. In addition, a thorough description of the owner's complaint of a change in or decreased performance provides valuable insight into the underlying problem, bearing in mind that often in the early stages little or no lameness may be present. Eighty-nine of 118 (75%) team roping horses had a history of lameness, and 29 (25%) had an owner complaint of decreased or altered performance.¹ The type of performance change differed between horses used for heading or heeling (Figures 120-1 and 120-2).

Fig. 120-1 • A header roping the steer and making a 90-degree turn to set the steer for the heeler. The weight of horse and rider results in excessive loading of the right forelimb of the head horse (gray horse).

Fig. 120-2 • A heel horse stopping after the heeler throws his rope. Note the flexion of the hock joints during the stop and the extreme forward placement of both hindlimbs.

Lameness Examination

Team roping horses experience many of the same problems as any of the Western performance horses. In the heading horse, the right forelimb is placed under tremendous force after the steer is roped and just before turning 90 degrees. The right forelimb is placed cranially and laterally to decelerate and brace against its forward motion and the weight of the steer, thus placing tremendous strain on this limb (see [Figure 120-1](#)). A study reported that horses used for heading had significantly more right forelimb lameness (72%) than heeling horses (43%).¹ The heading horse also had significantly more bilateral forelimb lameness (25%) compared with the heeling horse (9%).¹ Heeling horses that did not turn properly into the steer after it switched directions often had left forelimb lameness.¹ The distal tarsal joints are loaded with the rider's weight, the horse's weight, the deceleration of the full-speed forward motion, and the weight of the steer as primarily rotational forces. This occurs as the horse is asked to set and get under the steer and pull the steer's weight forward across the arena. After a successful catch by the heeler, the heading horse must face or spin around to the right while the hocks and distal hindlimbs are loaded as described, and do so with the addition of a backward motion to maintain tightness of the rope. Although more forelimb versus hindlimb musculoskeletal problems were observed in horses used for heading, distal hock joint pain and osteoarthritis (OA) were the most common problems observed in the hindlimbs.

The heeling horse often has a similar history, with problems in the heeling box, not making the corner properly as the steer is set and turned, or nickering and bouncing out of the stop at the completion of a run while maximal tension is on the ropes. Clinical examination often reveals pain on palpation of the caudal lumbar area, the gluteal muscles, and over the point of both hips. This pain often is accompanied by the owner complaint that the horse is sore in the kidneys. If only the distal tarsal joints are involved, effusion usually is not detectable, but

the horse may be reluctant to allow palpation of the medial aspect of the tarsus, as if anticipating pain. The dorsomedial distal aspect of the tarsus may be enlarged. High-quality radiographic examination of the hocks is essential. Intraarticular analgesia is often ineffective because the horse has developed performance problems in response to the pain experienced during every run, and the pain is anticipated, even though the area has been blocked. Thus horses become intractable in the roping box because they dread the pain that they will experience during the run. However, horses often respond well to intraarticular therapy when they realize, after several runs, that the pain has been lessened or stopped. The most common musculoskeletal problems causing lameness in horses used for heeling were (1) left forelimb palmar foot pain, (2) distal tarsal joint OA, (3) palmar foot pain and distal tarsal joint pain, (4) left forelimb pastern joint OA, and (5) hindlimb fetlock OA.

Diagnosis and Management of Specific Lameness

Palmar Foot Pain

Given the usual QH conformation of large body size and small feet or short, upright pastern conformation, navicular disease and injuries to structures within the palmar aspect of the foot are common. Right forelimb or bilateral palmar foot pain and left forelimb palmar foot pain were the most common problems identified in heading and heeling horses, respectively. Palmar foot pain results in a slowly progressive lameness, often bilateral, and horses may initially respond to intraarticular medication of the distal interphalangeal (DIP) joint, NSAIDs, and corrective shoeing. Soft tissue injuries of the palmar aspect of the foot (e.g., injury of the distal sesamoidean impar ligament [DSIL], a collateral ligament of the DIP joint, or the deep digital flexor tendon [DDFT] in the region of the navicular bone) are also common in heading horses and usually are acute, occurring during a roping event. Lameness is improved by perineural analgesia of the palmar digital

nerves or intraarticular analgesia of the DIP joint. Often no radiological abnormality is apparent. Diagnosis of the specific structure injured can usually only be determined by magnetic resonance imaging (MRI).

The diagnosis of palmar foot pain is not complicated, but determining which structure is damaged can be challenging. Diagnosis is based on a combination of historical data and the response to perineural and intraarticular analgesia, high-quality radiographs, and possibly advanced diagnostic techniques such as nuclear scintigraphy, computed tomography, or MRI. Severity and duration of the lameness, the horse's activity, potential owner compliance, and the experience of the owner's farrier should be considered when determining therapy. The horse's hoof wall quality, conformation, environment, and occupation all affect treatment.

A thorough musculoskeletal examination should include palpation of the digital pulse amplitudes and assessing the hoof capsule for increased heat. In 97% of 23 horses with palmar foot pain there was increased digital pulse amplitude in the most severely affected limb. Hoof tester evaluation can be beneficial in determining pain location. Pain involving the navicular area is identified by application of intermittent hoof tester pressure over the middle third of the frog, which results in persistent non-fatigable reflex withdrawal of the hoof from the examiner. However, false-negative results may occur, especially during periods of dry weather when the horse's feet are excessively hard or in horses with thick soles and hard frogs. It is important to assess whether the withdrawal reflex is resulting from real pain and not a whimsical reaction by the horse. The results from both front feet should be compared. Horses with an injury of the DSIL or the insertion of the DDFT seem particularly sore with hoof tester pressure near the junction of the middle and dorsal thirds of the frog. Horses with underrun heels, bruised heels, or damaged laminae in the heel area often have more pain over the affected heel. It is important, if possible, to differentiate peripheral versus central hoof pain with a thorough hoof tester examination.

Many of the middle-aged roping horses diagnosed with palmar foot pain have moderate to severe radiological lesions of the navicular bone. My initial treatment involves correcting any existing hoof imbalance. I apply a 2-degree wedge pad or wedge shoe, which decreases the pressure on the navicular area by about 25%. If the horse's foot was imbalanced and/or poorly shod, then correcting these problems combined with systemic NSAID therapy (phenylbutazone 1 g twice daily for 10 days) and rest may temporarily resolve the lameness. If the owner cannot rest the horse or the feet are properly shod, then I medicate the DIP joint using a combination of 9 mg of triamcinolone acetonide, 10 to 20 mg of hyaluronan, and 125 mg of amikacin.² Postinjection care involves 4 to 5 days of no roping and NSAID therapy (phenylbutazone 2 g daily for 5 days). Approximately 60% of horses respond to DIP joint medication and, depending on severity of disease and level of work, will remain sound for 4 to 6 months. If the horse does not respond to DIP joint medication, then I medicate the navicular bursa with 10 mg of hyaluronan and 9 mg of triamcinolone acetonide, or if a severe bony lesion exists, I use 20 mg of methylprednisolone acetate plus 125 mg of amikacin. I reserve navicular bursa medication only for

those not responding to DIP medication and known not to have an acute soft tissue injury (e.g., a DDFT lesion). Horses with chronic collateral sesamoidean ligament pathology, identified by the presence of a spur on the proximomedial or proximolateral aspects of the navicular bone, usually do not respond to DIP joint medication but do respond to treatment of the navicular bursa. I caution the owner that navicular bursa injections are invasive and may lead to subsequent DDFT pathology and/or rupture. Palmar digital neurectomy is the last resort in treating horses with palmar foot pain because of its short-lived results (average 2 years of soundness) and numerous complications, such as severe infection, DDFT rupture, and DIP joint subluxation.

Soft Tissue Injuries

Ligament or tendon injury occurred in about 15% of heading horses, especially in the right forelimb, and in about 10% of heeling horses, usually in the left forelimb.¹ The structure affected varied, but the suspensory apparatus, the accessory ligament of the DDFT, DDFT, superficial digital flexor tendon (SDFT), and the distal sesamoidean ligaments were all involved. These injuries usually cause lameness of varying degrees, and diagnosis by clinical examination is straightforward. Ultrasonography should be used to confirm the diagnosis. Distal sesamoidean ligament injury may be more difficult to diagnose but often results in acute, moderate to severe lameness (grade 2 to 3 of 5) after a run, associated with pain on palpation of the palmar aspect of the pastern. Perineural analgesia of the palmar digital nerves may improve the lameness, but analgesia of the palmar nerves at the base of the proximal sesamoid bones is needed for complete soundness. Fractures of the middle phalanx are also common; therefore the horse should be examined by radiography and ultrasonography. Ultrasonographic evidence of enlargement or reduction in echogenicity in the straight (SSL) or oblique sesamoidean ligaments (OSL) is diagnostic (Figure 120-3). Radiological examination is usually negative if lameness is acute; however, chronic injury is often associated with enthesioid new bone on the palmar aspect of the proximal phalanx or on the proximopalmar aspect of the middle phalanx associated with OSL or SSL injury, respectively.

In hindlimbs, deep digital flexor tendonitis, tenosynovitis of the digital flexor tendon sheath, and proximal suspensory desmitis (PSD) are common, especially in the left hindlimb of head horses. When turning to face the steer, the head horse turns 180 degrees at fast speeds, putting a rotational torque on the distal aspect of the left hindlimb (Figure 120-4).

The management of roping horses with these soft tissue injuries varies with which structure is affected and severity of the lesion, although the initial treatment is similar. The first 2 weeks consist of daily ice therapy for 20 minutes two to three times per day, NSAIDs (phenylbutazone 1 g twice daily for 7 days), stall rest with 10 minutes of handwalking, and a support bandage. This is followed by a variable period of stall rest with 15 to 20 minutes of daily handwalking. When the horse is sound and there is 80% resolution of any lesion seen using ultrasonography, a controlled exercise program is initiated to strengthen the affected structure (Box 120-1).

The horse remains confined until the controlled exercise program is completed. Lameness and ultrasonographic

Fig. 120-3 • Transverse (left) and longitudinal (right) ultrasonographic images of the midpastern region of the right forelimb of a head horse. There is a hypoechoic lesion in the straight sesamoidean ligament (arrows) (SSL). SDFT, Superficial digital flexor tendon; DDFT, deep digital flexor tendon; OSL, oblique sesamoidean ligament.

BOX 120-1

Exercise Regimen after Mild Injuries to Forelimb Suspensory Ligament or Accessory Ligament of the Deep Digital Flexor Tendon

Weeks 1-2	The horse is given stall rest or a small run (6 × 10 m) with support bandage on the limb, ice therapy, and nonsteroidal antiinflammatory drugs.
Weeks 2-6	Length of time depends on severity of the lesion and structure affected. Horses are rechecked and ultrasonographic examination is performed at 3-month intervals until the horse is sound and the lesion is 75% to 80% healed. The horse is handwalked 10 minutes daily.
Weeks 6-8	Confinement is continued with 15 minutes of handwalking twice daily.
Weeks 9-12	Confinement is continued with 30 minutes of handwalking daily.
Weeks 13-16	If horse is sound at the trot, then confinement is continued, but the horse is walked under saddle or is ponied 15 minutes a day plus 5 minutes of trotting. Five minutes of walking and trotting are added every third day. The horse is reexamined by ultrasonography before returning to roping activity.

examinations are repeated before the horse returns to roping activity or turnout.

Distal Hock Joint Pain

OA of the distal hock joints is common, and heeling horses seem especially at risk. Most respond well to intraarticular medication of the centrodistal and tarsometatarsal joints. Middle-aged horses with moderate or severe OA are treated with 40 mg of methylprednisolone acetate and 125 mg of amikacin per joint. Younger horses or horses with mild to no radiological lesions are treated as above except 10 mg of hyaluronan is added to each joint. Postinjection care is 7 to 10 days off before returning to roping. The toes are squared on the hindlimbs to ease breakover and decrease torque on these joints.

Back and Pelvic Region Pain

Injury to the back and pelvic area is seen, especially in heading horses. Strain or tearing of the sacroiliac ligaments or epaxial musculature can occur. Radiographic evaluation is difficult and often unrewarding, but ultrasonographic examination may reveal longissimus lumborum and gluteal muscle tearing and can be used to evaluate the sacroiliac area. Lameness predisposing to back pain must be eliminated. Rest combined with topical heat (hot towels) and dimethyl sulfoxide or diclofenac (Surpass, IDEXX

Pharmaceuticals, Inc., Greensboro, North Carolina, United States) helps many horses, but often months of rest are needed before the pain is eliminated. Treating the painful areas with local injections hastens the recovery time. I prefer a combination of 5 mL of methylprednisolone acetate, 5 mL of Sarapin, and 5 mL of prednisolone diluted with 30 mL of mepivacaine and then depositing 3 to 5 mL in several sites around the painful muscle or ligament. The horse is given 2 to 3 weeks of light riding, with no roping activity, and then is reevaluated by ultrasonography. Most horses return to roping activity within 4 weeks from the time of injury.

Obviously all team roping horses are also susceptible to any of the same injury problems that other equine athletes experience. Most of these injuries produce overt lameness, and diagnosis is usually straightforward.

Shoeing Considerations

Because roping horses are often middle-aged, are used frequently, and commonly have palmar foot pain, maintenance of proper hoof balance is critical in keeping these horses sound. Long toes and collapsed heels are common. The heels grow too far forward and are left unsupported and thus are at risk of abnormal concussion. We recommend trimming the heel back to the widest part of the frog and setting the shoe further back on the foot; thus the heels of the shoe end at the widest aspect of the frog. Care must be taken to fit the front shoes properly so that little of the medial side of the shoe is exposed because head horses have a tendency to grab this portion of the shoe and pull off a shoe, especially the left front shoe. Easing the breakover of the limb can be accomplished by rockering the shoe. A rim shoe or steel natural balance shoe provides good traction and allows an easier breakover by the rounded and rockered toe region of the shoe construction. The natural balance shoe has a wider web than a normal shoe and is beneficial for horses with sore feet acquired from performing on harder ground. If trimming alone cannot establish a correct hoof-pastern angle, a 1- to 2-degree wedge pad is recommended. We prefer a cutout pad because a full pad often traps moisture and can lead to thrush. Care must be taken to avoid pad pressure over the central region of the frog in horses with navicular pain.

In horses with deep digital flexor tendonitis, we recommend applying a 2- to 3-degree wedge pad for the initial 4 to 5 months of rest to decrease tension on the DDFT. The wedge is reduced gradually over three shoe resets, once the horse is sound. In horses with distal hock joint pain, we try to ease breakover of the hind feet by squaring the toes or by setting the shoe back under the toe 0.3 cm. Avoiding any type of trailer or extension on the rear shoes is also preferable, especially for a heading horse, because this can aggravate pain associated with distal hock OA.

CALF ROPING AND BREAKAWAY ROPING HORSES

Description of the Sport

Calf roping originated on ranches of the Old West when sick calves were roped and tied down for medical treatment. Success in calf roping depends on the teamwork between a cowboy and a horse. After the calf is given a

head start (like a scoreline in team roping), horse and rider chase the calf, and as the rider ropes the calf, the rider dismounts and runs to the calf. As the rider dismounts, the horse must sit back on its hind end and come to a sudden stop, which takes the slack out of the rope and stops the running calf. This allows the cowboy to catch the calf and throw the calf to the ground, termed *flanking the calf*. Once on the ground, the cowboy ties three of the calf's legs together with a pigging string. The horse is trained to "work the rope" as the cowboy ties the calf, meaning to back up if needed to keep the rope tight, thus keeping the calf still for the rider to tie. When the cowboy completes his tie, he throws his hands up in the air as a signal to the judge that his run is complete. The calf must stay tied for 6 seconds. A 10-second penalty is added if the calf roper breaks the barrier at the beginning of the run. An 8- to 9-second run is considered good, and Jeff Chapman of Athens, Texas set the arena record in 1997 when he roped and tied a calf in 6.8 seconds.

Breakaway roping is similar to calf roping except the participants are women and children and the rider does not dismount and tie the calf. Instead, the calf is given a similar score or head start, and the horse and rider chase the calf and rope it around the neck. The rope used for breakaway roping has a quick-release device on it so that when the rope becomes tight, it snaps open and the calf runs free. After the calf is roped, the horse stops abruptly, the rope tightens and breaks away, and time is called. The rider remains on horseback. A typical breakaway time is 3.0 to 4.0 seconds.

Conformation

QHs are used for calf roping and must be athletic and well trained. Because the rider must dismount during calf roping, calf horses are usually not tall, often 14.2 or 14.3 hands high. Calf horses also have wide-base and muscular frontquarters and hindquarters. Many ropers believe that the performance demands on a calf horse are greater than those of a team roping horse.

Historical Data and Poor Performance

Calf roping and breakaway roping horses often show an alteration in performance before an observable lameness. There are no scientific studies specifically evaluating calf and breakaway roping horses. However, anecdotally the most common owner complaint is that a calf horse quits "working the rope," that is, after the calf is roped, the horse does not want to back up and keep tension on the rope for the rider to catch and tie the calf. This is usually associated with hindlimb lameness. Another common complaint is that the horse ducks to the right or left after the calf is roped instead of stopping in a straight line. If the horse ducks to the right, this is usually because of left-sided pain that the horse is trying to avoid. A horse that will not run hard to the calf usually has front foot pain.

Diagnosis and Management of Specific Lameness

Calf horses have lameness similar to that of team roping horses with a few exceptions. Hindlimb lameness is more common in horses used for calf roping. OA of the distal hock joints is the most common problem, but stifle lameness also occurs frequently, such as collateral ligament or meniscal injury. However, diagnosis is usually not possible

until after bony changes are seen radiologically, months after the initial injury. Bony reaction at the proximal medial aspect of the tibia is diagnostic. With rest, NSAIDs, and intraarticular medications, these horses often can return to roping, but at a lower level, perhaps as a calf roping horse for a child or beginner. Hindlimb proximal suspensory desmitis, traumatic fetlock OA, and fractures of the proximal sesamoid bones and middle phalanx are common. The most common forelimb lameness is palmar foot pain, often resulting from improper shoeing.

Shoeing Considerations

The same shoeing considerations are used for balance and protection of the navicular region in the forelimbs as described for team roping horses. Rim shoes or half round shoes are commonly worn on the front feet. In the hindlimbs if the toes of the feet are too short, so that the horse has a broken forward hoof-pastern axis, then the hind toe digs deep into the ground and the limb stops abruptly, causing sudden torque on the distal aspect of the limb. Having more toe length and a shoe that fits full with the heel branches of the shoe extending to the heel bulbs is preferable, so that the horse slides as it stops. This not only protects the heel bulbs from the ground surface, but it also puts less strain on the distal aspect of the limb. Horses used for calf roping often wear skid boots, protective leg gear aimed at minimizing friction between the ground surface and the plantar aspect of the hindlimb fetlock joints, because the horse skids to a stop.

■ THE REINED COW HORSE

*Van E. Snow**

The National Reined Cow Horse Association was initiated in 1949 as the California Reined Cow Horse Association and changed its name in 1970. The purpose of the association is to preserve the training traditions of the vaqueros, the horsemen of early California, who trained their horses for ranch work. As a result of selective breeding and refined training techniques, reined cow horses today are able to achieve more with livestock than was ever thought possible.

The National Reined Cow Horse Association held its first Snaffle Bit Futurity in 1970 in Sacramento, California. Bobby Ingersoll, a renowned cow horse trainer, had the idea to showcase the best all-around cow horses in the world. The competition involves showing the horse in three different disciplines: herd work (cutting), rein work, and cow work (working a cow down a fence). In the Snaffle Bit Futurity, the top 20 horses from the first round of competition come back and do another round over 2 days, starting again with even scores. The sport of reined cow horse has evolved from 1970, when 27 horses competed for \$3900, to now when hundreds of horses compete at their annual futurity for nearly \$1 million.

The professionals compete on numerous horses in four divisions: snaffle bit, hackamore, two rein, and bridle. Competition consists of numerous levels, including professional, nonprofessional, amateur, and limited open. An auction is held each year at the reined cow horse futurity

at which horses that range from 1 to 12 years of age and breeding stock horses are available for sale.

Affiliate groups of the National Reined Cow Horse Association are organized in Canada, Germany, Belgium, and Australia, and a strong interest in the group exists in most of Europe and in South and Central America. No restrictions exist as to the breeds allowed to compete in the futurities. Numerically the American Quarter Horse dominates, but Paint horses often compete successfully, and an Appaloosa has won.

The competition requires that a horse be accomplished in its ability to run, stop, turn, and “read” and control a cow. These horses also must have a high level of endurance. These qualifications do not necessarily dictate a particular body type, but a reined cow horse tends to be a taller, leaner horse than a cutting horse. Stallions, mares, and geldings compete equally, as do all genders and age groups of riders.

Reined cow horses typically begin training when they are less than 2 years old and start to compete at 3 years of age. They have about 20 months to learn all of the events and to become conditioned well enough to withstand the rigors of competition. This requires that the training surface, shoeing, and judgment of the trainer be optimal throughout the 20-month period.

Most trainers have become knowledgeable in the prevention and the early detection of lameness. Musculoskeletal evaluations are done quarterly on the futurity prospects, beginning in the fall of the 2-year-old year. These evaluations include a complete lameness evaluation, including flexion tests. At this time, good baseline information on each horse is established, and future insidious problems can be detected before they become unmanageable. In the past, it was commonplace for a trainer to blame himself or herself or the horse’s attitude for not being able to accomplish a certain task, when in fact low-grade lameness was developing. The trainer would continue to train the horse, and often a serious lameness would develop. For a trainer to suspect a subtle lameness and to have the horse evaluated is much more common now. Lameness detected at this point is usually manageable.

A reined cow horse continues to compete beyond 3 years of age. As 4-year-olds, they can continue in the snaffle bit or begin in the hackamore or bridle class. The 5-year-olds are shown in the hackamore or bridle class, and the 6-year-olds compete in the bridle class. Hackamore and bridle horses compete in the reining and cow work divisions, but they do not do herd work. The intention is to finish a horse’s education by the time the horse is 6 years old.

TRAINING SURFACES

The training surface has a strong influence on lameness in terms of incidence, degree of severity, and type of injury. In general, an arena or round pen is best constructed as follows: the original ground is graded to a 1.5% grade from one corner to the other and is compacted to 95%. A 15-cm thickness of base material such as limestone rock dust is then added, watered, and compacted to 95%. The type of base used is dictated by what is available in the area, but it should be smaller-sized particles (not small rocks) that have interlocking edges. A 1.5% grade should be

*Deceased.

maintained. Sand is then added to the top of the base to a thickness of at least 5 cm and not more than 12 cm in the arena, and from 10 to 15 cm in a round pen. Adding the sand at the minimum levels first and then adding more later if necessary is recommended. In general, less injury occurs with thinner layers of sand, but performance may be enhanced with thicker layers of sand. Fine beach sand is the best because it has low abrasive characteristics and is light. These qualities are important because the sand gets between the skin and protective boots and also comes in direct contact with the back of the pasterns and fetlocks. If the sand is coarse and abrasive, it damages the skin and causes lameness. The density of the sand is important because a horse has to push the sand during sliding stops, and if the sand is too heavy, it causes injury and destroys the horse's confidence.

Water content of the training surface is also an important consideration. In general, applying water a few hours before use is a good idea, so that the water is distributed evenly. If the training surface is too deep with sand or if the base is not consistent, I see more soft tissue injuries such as tendonitis, suspensory injuries, curbs, and sprained backs. If the training surface is too hard, I tend to see bone injuries such as osteitis of the distal phalanx, navicular syndrome, sesamoiditis, or fractured proximal sesamoid bones.

THE RELATIONSHIP OF TRAINING TO LAMENESS

The types of injuries commonly seen tend to vary as the training progresses. The young 2-year-olds have hoof and sole problems during the initial breaking process, before they are shod, associated with an increased digital pulse amplitude and sensitivity to hoof testers. Subchondral bone cysts in the medial femoral condyle and osteochondrosis of the fetlock may manifest at this time. Chip fractures, present but unnoticed when the horse was a foal or yearling, may become clinically apparent when ridden work starts.

The work during the latter half of training for a 2-year-old involves more speed and collection, and low-grade lamenesses may develop that later become persistent problems. These lamenesses include suspensory desmitis, navicular syndrome, and hock and stifle pain. The 3-year-old year involves even more collection, cow work at speed, and harder stops. We generally see a continuation of the 2-year-old problems, if they are not managed well, and also more acute injuries to soft tissue and chip fractures of the fetlock and carpus.

CONFORMATION AND LAMENESS

Conformation has an effect on the development of lameness, but I believe that conformation often is overemphasized. The component of conformation that has the biggest effect on soundness is body conformation and the degree of balance in motion. I have seen many horses whose conformation was not impressive when viewed at a standstill but were impressive when evaluated in motion. Balance in motion is that somewhat immeasurable quality that gives one the impression that the horse could jump, stop, turn, or do almost anything on any given stride without effort. In my experience, these horses remain sound while performing to an exceptional level, whereas horses that

have less balance suffer more frequent injury. Although static conformation related to lameness is important and should be evaluated, in my opinion, conformation in motion is equally important.

The most common conformation problems that I see are toed in and toed out. These problems predispose the horse to lameness but are present to some degree in nearly all horses. Most often these conformational abnormalities are associated with injury to the suspensory ligament (SL) and also can be associated with injury to the collateral ligaments of the digit. I try to manage these conformation faults before they cause injury to the horse by trimming and shoeing. A horse that toes out initially contacts the ground with the outside toe quarter with improper trimming. The hoof then slides along the ground and begins to rotate the toe out. The inside heel bulb then makes contact with the ground, and the hoof rotation stops. However, this rotational force continues up the limb and places unnatural strain on the soft tissues below the carpus and eventually causes damage. I recommend removing more wall from the hoof at the point of contact and beveling the toe so that breakover is accomplished easily over a wide area. My goal is to get the entire hoof to contact the ground evenly and eliminate the rotational force. Horses that toe in generally contact the ground at the inside toe quarter. Horses with this problem need more hoof removed from the inside toe, the goal being to cause the foot to land flat.

LAMENESS EVALUATION

I begin the lameness examination by obtaining as complete a history as possible. I establish the duration of lameness; any change in lameness, if the horse has been rested or kept in work; any response to treatment; alteration in lameness with work; when the horse was last trimmed and shod; any changes in footing, type of work, or shoeing; if lameness was associated with turnout or work; if the horse has received any intramuscular injections; if the horse kicks the paddock or stall; if the horse is turned out with others; if the horse stumbles; any known trauma; whether the lameness occurred insidiously or suddenly; and if the horse stands normally. Generally, the best history is obtained from the grooms and trainer, although some owners can provide information.

I watch the horse at the walk, trot, and canter, loose in a 9-m round pen, and on firm footing on a 2% slope. The degree of lameness often is amplified when the horse is loose, on hard ground, and allowed to work on a slight slope. Some lameness characteristics are best seen at a slow trot and some at an extended trot. The round pen enables one to evaluate the horse's ability to hold leads. Detecting low-grade ataxia is also easier when the horse works free, especially during downward transitions.

Lameness may be manifest in how a horse does a sliding stop; lameness may be accentuated after several sliding stops from a canter. A horse may slide stronger on one hindlimb than the other. The complaint is often made that a horse is not stopping as well as previously, although lameness is not noticed. A horse may begin a sliding stop normally but then pick up the painful limb halfway through the stop and replace it. The stop is not held evenly. The stop becomes normal if pain is removed by local analgesia.

Another common situation occurs when a horse is cutting a cow; the horse runs off at one end or does not come back with the cow as strongly at one end. The hindlimb farthest from the cow before the weak turn is generally the lame limb. If this horse is asked to do rollbacks in a round pen, the horse is much weaker when it reverses direction one way. Generally, the hindlimb on the outside of the circle after the weak rollback is the lame limb.

Competition is now so great that the difference between winning and losing is sometimes a matter of which horse feels the best. Performance diminishes before outright lameness is noted. Hindlimb lameness is particularly common in reined cow horses because of hock or stifle pain or proximal suspensory desmitis.

Flexion tests include flexion of the digit in all limbs and carpal, hock, and stifle flexions. Notes are made on the results and whether the horse resented flexion. The digit is flexed in an oblique plane (applying medial and lateral torque), and any resentment or decreased elasticity is noted.

All the soft tissue structures are palpated, and any enlargements and sensitivity are noted. Hoof testers always are applied to the front feet, as well as to the hind feet of horses with hindlimb lameness. Any lameness or weakness is classified in degrees (grade 1 to 5); by the limb involved; by weight bearing or non-weight bearing or mixed status; by the effect of walking in a circle or on a straight line, on an incline or decline; by flexion tests; and by the effects of prolonged digital pressure over sensitive areas.

If lameness is serious enough possibly to be caused by fracture, radiography is performed first; otherwise, diagnostic analgesia is used to establish the source of pain. Intraarticular analgesia is more specific than regional analgesia, which can be done at a later time if necessary; therefore I often start with intraarticular blocks, especially in forelimbs. I rely on the flexion tests to direct the start point. If flexion of the distal limb is normal but carpal flexion is positive, I usually use perineural analgesia of the proximal palmar metacarpal and palmar nerves (high four-point). If lameness persists, I perform intraarticular analgesia of the carpus. If flexion of the distal limb is positive, I perform intraarticular analgesia of the distal interphalangeal (DIP) joint first and then proceed to the pastern and fetlock joints if necessary to eliminate the pain causing lameness. If intraarticular analgesia is not helpful and the flexion test is still positive, I perform perineural analgesia of the palmar digital nerves, followed by the digital nerves at the base of the proximal sesamoid bones (PSBs) and later a "low four-point block." Knowing whether the problem is articular is useful because horses with articular problems are often more amenable to treatment.

For intraarticular analgesia I do a three-step povidone-iodine (Betadine, Purdue Products L.P., Stamford, Connecticut, United States) and alcohol skin preparation and use sterile gloves. I place a subcutaneous bleb of local anesthetic solution before injection and combine local anesthetic solution with gentamicin sulfate (40 mg).

In a hindlimb I usually use perineural analgesia proximal to the fetlock, local infiltration around the region of the origin of the SL, intraarticular analgesia of the centrodistal and tarsometatarsal joints separately, and intraarticular analgesia of the femoropatellar and medial femorotibial joints. The lateral femorotibial compartment

rarely is involved. If the response to a low four-point block is positive but the response to plantar nerve blocks at the base of the PSBs is negative, intraarticular analgesia of the metatarsophalangeal joint is performed the following day.

IMAGING CONSIDERATIONS

Once the region of pain is localized, the area is examined using radiography and ultrasonography to identify the exact structure that has been damaged and to assess the degree of damage. The more specific I can be at this point, the more reliable the prognosis and treatment are. If the diagnosis is not specific, scintigraphy often is used. Generally, a differential diagnosis list is generated based on the physical examination. Developing a therapeutic plan based on a tentative or vague diagnosis is a mistake. Nearly all diagnoses are tentative until the pain has been localized as specifically as possible through the use of diagnostic analgesia and appropriate imaging.

PROCEEDING WITHOUT A DIAGNOSIS

Sometimes the site of pain causing lameness cannot be discovered, even after all the joints and nerves have been blocked and a complete scintigraphic examination has been performed. I then treat the horse for myofascial pain with drugs or chiropractic therapy. If the horse responds to these therapies, then this is indirect evidence of the cause. Another possible cause is equine protozoal myelitis (EPM). Horses with EPM may show chronic lameness without other neurological signs.

LAMENESS AND SHOEING CONSIDERATIONS

Proper foot balance is critical to resolving all lameness problems successfully. The foot should be trimmed to land evenly. Any medial-to-lateral imbalance should be removed by trimming. If the point of contact is the lateral toe quarter, then enough of the lateral wall should be removed so the foot lands flat. The foot should be trimmed or a wedge used to achieve a hoof angle that is the same as the pastern angle (about 55 degrees in forelimbs and 57 degrees in hindlimbs). A square-toed shoe that has a wide bevel, which extends from the medial to lateral toe nail holes, commonly is recommended and is useful. The shoe should be set back so the dorsopalmar axis is shortened. The heels are trimmed so the shoe comes in contact with the wall at the widest section of the frog. These specifications are designed to remove rotational forces up the limb that occur in horses with medial-to-lateral imbalances, to provide mechanical advantage to the palmar/plantar aspect of the limb that occurs in horses with a long toe and low heel, and to reduce concussion to the digit that occurs in horses with the two-phase foot impact associated with foot imbalance.

An egg bar shoe is used for horses with moderate to severe tendonitis, suspensory desmitis, or an apical PSB fracture. A reverse shoe is used sometimes for horses with navicular syndrome, ringbone, sesamoiditis, suspensory desmitis, tendonitis, constricted palmar/plantar annular ligament, carpalitis, and tarsitis. Horses with bruising in the sole are shod with soft dental acrylic pads. Horses with heel and quarter cracks are managed with egg bar shoes.

TEN MOST COMMON LAMENESS CONDITIONS IN THE REINED COW HORSE

1. Suspensory desmitis
2. Osteoarthritis of the centrodistal and tarsometatarsal joints
3. Navicular syndrome
4. Hoof-related problems such as bruises, abscesses, and cracks
5. Superficial digital flexor tendonitis
6. Subchondral bone cysts, osteochondrosis, and traumatic injuries of the stifle
7. Fetlock arthritis
8. Sesamoiditis
9. Distal interphalangeal joint synovitis or osteoarthritis
10. Osteitis of the distal phalanx

TREATMENT OF LAMENESS

Suspensory Desmitis

For horses with suspensory desmitis, it is important to optimize foot balance as previously described. Corrective shoeing is designed to minimize any further physical damage and therefore prevent further pain and inflammation. Other treatments provide short-term results and are aimed at reducing the existing inflammation.

Horses with minor to moderate fiber disruption are treated with perilesional injections of Sarapin and corticosteroids. If the lesion is proximal, a sterile skin preparation is recommended, with the addition of gentamicin sulfate (40 mg) in case the carpometacarpal joint is entered inadvertently. The drugs are injected under the loose tissue between the SL and the accessory ligament of the deep digital flexor tendon. Middle carpal joint pain may occur concurrently and is treated using intraarticularly administered corticosteroids, provided that no radiological abnormalities are apparent. Physical therapy in the form of electrical stimulus modalities or low-level light laser therapy is started 3 days after injection and continued as needed through the intended competition. Magnets of 600 to 1200 G placed over the site have been used successfully and are kept in place for 60 days and then as needed for soundness.

The lesion is monitored monthly using ultrasonography. If conservative treatment fails, extracorporeal shock wave therapy (ESWT) is used and administered with the horse under general anesthesia. Up to four treatments have been used, combined with rest for 60 to 90 days.

Centrodistal and Tarsometatarsal Joint Pain

Intraarticular injection of corticosteroids is effective at relieving pain and inflammation in the centrodistal and tarsometatarsal joints. Horses are allowed to rest for at least 10 days after injection, and then work gradually is increased as soundness dictates. The systemic use of hyaluronan and acetylglucosamine is helpful for maintenance. Orally administered chondroitin sulfate and glucosamine products also have been useful. If medication is ineffective, joint drilling or forage to induce joint ankylosis, or periarthritic ESWT can be used effectively.

Navicular Syndrome

Navicular syndrome is diagnosed based on a positive response to palmar digital analgesia and analgesia of the DIP joint, radiography, and scintigraphy. Radiology can be misleading, and in my opinion scintigraphy is the most reliable method of diagnosis. Corrective shoeing is essential. Isoxsuprine hydrochloride (600 mg) is given orally once daily for 60 days. Aspirin (15 g) also is given orally once daily for 60 days. If this combination provides relief, it is continued for another 60 days or until the horse finishes the futurity season. Injection of the DIP joint with corticosteroids, or a combination of corticosteroid and hyaluronan, often provides temporary relief (about 30 days).

If a horse fails to respond to corrective shoeing and medications, ESWT is indicated and has been effective, except in horses with enthesioid new bone at the attachment of the collateral sesamoidean ligaments. Palmar digital neurectomy is used as a last resort.

Traumatic Hoof Injuries

Horses with bruises and cracks in the hooves respond well to egg bar shoes with soft dental acrylic pads or metal pads. A horse with a quarter crack is treated by trimming the wall palmar/plantar to the defect, so that no contact is made with the shoe, that is, floating the heel. The air gap is up to 6 mm deep and is reopened daily using a hacksaw blade to relieve pressure between the hoof wall and the shoe until the defect has grown out. If the crack is moving and bleeding, a copper patch is attached to the wall with screws to span the defect and therefore stabilize it.

Superficial Digital Flexor Tendonitis

Ultrasonography is used to characterize size and position of the lesion in horses with superficial digital flexor tendonitis. If a lesion is small, the owner or trainer usually decides to continue preparing for the futurity. It is important to try to determine the circumstances that caused the lesion to develop to eliminate further damage. Possible causes for tendonitis include poor hoof balance, deep footing, fatigue, speed, overexertion from working a difficult cow, uncontrolled exercise (turnout), interference from hindlimbs, tight bandages, poorly fitting support boots, and hanging a leg on a hot walker, tie rope, or fence.

Therapy for tendonitis involves depositing corticosteroids in the loose subcutaneous tissue in the proximity of the lesion. The leg is wrapped in a gelocast for 3 days and then is treated with ice and laser or electrical stimulus therapy. The horse is walked in hand or under saddle for 15 minutes twice daily for 7 days. Training then is resumed. The leg is maintained in a support wrap continuously. Shoeing, good footing, and conservative training are critical to the healing process.

Stifle Pain

If no abnormalities are detected in the stifle radiologically, the affected joints are treated with intraarticularly administered corticosteroids and hyaluronan. The horse is prescribed weekly injections of systemic acetylglucosamine, which continue through the futurity. Subsequent intraarticular injections are not performed sooner than 6 months and preferably not at all.

If radiological evidence of osteochondrosis of the trochlear ridges of the femur exists, the same therapy is effective.

The prognosis for horses with subchondral bone cysts of the medial femoral condyle is dismal, and I do not recommend that these horses continue training to be futurity horses.

Metatarsophalangeal Joint Pain

Metatarsophalangeal joint pain may be caused by traumatic osteoarthritis, fracture of a PSB, sesamoiditis, fragments detached from the proximoplantar aspect of the proximal phalanx, or periarticular soft tissue injury. If no radiological lesions are present, the horse is treated with intraarticularly administered betamethasone and hyaluronan, followed by 10 days of rest. Systemic glucosamine is given every 2 weeks as maintenance therapy. Orally administered glucosamine and chondroitin sulfate also seem to be useful in managing metatarsophalangeal joint pain. Shoeing imbalances must be corrected concurrently.

Sesamoiditis

The foot must be properly balanced to treat sesamoiditis. Egg bar shoes with a square toe and a wide roll or bevel are used. The shoe is set back to minimize the leverage on the palmar/plantar aspects of the fetlock. The hoof angle is optimal when it matches the pastern angle. Isoxsuprine hydrochloride (600 mg) and aspirin (15 g) are given orally once daily for 60 to 90 days. Electromagnetic energy is applied to the affected region every other day for 3 months and thereafter as needed for soundness. The amount of training is dictated by the degree of soundness.

Distal Interphalangeal Joint Pain

The foot must be properly balanced to treat reined cow horses with DIP joint pain. Soft dental acrylic pour-in-type pads and shock-absorbing rim pads can be helpful. Intraarticular injection of a corticosteroid and hyaluronan is followed by the systemic use of acetylglucosamine and hyaluronan. It is imperative that training is continued on a soft surface.

Osteitis of the Distal Phalanx

Soft dental acrylic pour-in-type pads and shock-absorbing rim pads are used to treat horses with osteitis of the distal phalanx. The horse is treated with isoxsuprine hydrochloride (600 mg), aspirin (15 g), and phenylbutazone (2 g) given orally once daily for 60 days and then as needed for soundness. Training must be done in soft footing to reduce concussion to the foot. ESWT has recently been introduced to manage horses with osteitis of the distal phalanx. The Editors question whether shock waves can penetrate the hoof capsule, or whether they have adequate depth of penetration if administered via the heel bulbs.

BARREL-RACING HORSES

Robin M. Dabareiner

Barrel racing began in 1948 when a group of Texas ranch women started riding horses around a cloverleaf pattern of barrels and the fastest horse around the course was the winner. Barrel racing has evolved into a multimillion-dollar industry called the Women's Professional Rodeo Association (WPRA). From this original organization many

other barrel racing associations, which host numerous futurities for horses 4 or 5 years of age or younger and derbies for older horses, have arisen.¹⁻⁵ Now (from the WPRA website) "WPRA barrel racers compete for millions of dollars each year, culminating in twelve circuit finals rodeos held throughout the country, the Dodge National Circuit Finals Rodeo held in Pocatello, Idaho in April, and the Wrangler National Finals Rodeo held in Las Vegas each December." The major competitions are divided into rodeo, futurities, derbies, open jackpots, and professional levels. Futurities and derbies are classified by age of the horse. Open competitions are open to any horse or rider and are highly competitive. Within the open jackpots, a new classification of barrel racing has developed, termed a *3D* or *4D competition*, which includes a handicapping system that allows less experienced horses or riders to compete with seasoned horses and riders.

Barrel racing is a timed event with the clock beginning when a predetermined line is crossed. Three barrels (55-gallon steel drums) are positioned in a triangle or cloverleaf (Figure 120-5). The contestant must turn the left or right barrel first (most choose to turn the right-hand barrel first) in a manner that the path always crosses. The distance covered for the pattern varies with the size of the arena, but generally the distance from the starting line to the first

Fig. 120-5 • Diagram of barrel racing cloverleaf.

barrel is 14 to 18 m. The distance between the first and second barrel is 21 to 27 m and between the second and third barrel is 27 to 32 m. The horses must start at the alleyway or entrance to the arena, run at full speed to the first barrel, slow down and complete a 360-degree turn around the barrel, speed up and run to the second barrel, turn 360 degrees, head to the third barrel, turn 360 degrees, and then sprint to the finish line. The fastest time to complete the pattern varies with distance of the pattern and arena size, but a good run for a large arena pattern is 15 to 16 seconds. An electric eye timing system usually is used, and times are recorded in hundredths of a second. If a rider hits a barrel and tips it over, a 5-second penalty is imposed. If the horse and rider fail to negotiate the pattern correctly, they are disqualified. The arena is often leveled after each horse.

CONFORMATION

Horses are predominately American Quarter Horses (QHs) and Appendix horses (QH and Thoroughbred [TB] crosses), but occasionally TB, Paint, or Arabian horses are seen. Speed, quick acceleration, and agility to slow down quickly to turn the barrel are essential. Many barrel horses have QH racehorse pedigrees. Some prefer stockbred horses, which usually have a calmer personality. Geldings are preferred. Horses usually range from 14.3 to 15.1 hands. Barrel horses are not usually as muscular and wide based as calf roping horses. They usually have long, leaner muscle mass that provides the speed and flexibility needed to perform the 360-degree turns. In a recent retrospective study evaluating musculoskeletal problems in 118 horses used solely for barrel racing, the median age was 9 years (range, 3 to 19 years), median weight was 509 kg (range, 409 to 611 kg), and 73% were geldings and 27% were mares.⁶

TRAINING

Futurity competitions are popular because of the amount of prize money, and training usually starts at 2 years of age. Futurity horses often have short careers because of the pressure to perform at a high level of competition at only 4 to 5 years of age, resulting in advanced osteoarthritis (OA), often in the distal tarsal joints. Successful futurity horses seldom have long-term careers because of behavioral problems or performance-limiting injuries.

Horses that are 5 years of age or older, started slowly, and are allowed to mature before performing in serious competition may compete professionally for 5 years.² The average age of a professional barrel horse is 10 to 15 years. Horses may compete in 50 to 100 rodeos per year and spend much time traveling. An experienced barrel horse is trained by practicing turns but rarely uses the barrels because the horse learns to anticipate the pattern and tires of it. Many professional horses are ponied (led from another horse) or are ridden just enough to keep them fit for competition, but they are never really worked unless competing.

Older, semiretired horses that are well trained to the barrel pattern, but not fast enough for upper-level competition, may be used for a child or beginner. These horses do make repetitive barrel pattern runs in a practice pen for the rider to learn and often have use-related injuries, requiring much maintenance therapy to withstand the number of practice runs needed to teach a beginner.

HISTORICAL DATA AND POOR PERFORMANCE

Barrel racing is the one equine discipline that most riders train and ride their own horses. Unlike roping events where many variables exist (e.g., cow selection and partners), there are few variations in the barrel horse pattern or run. Size of arena and ground surface may affect the speed of the run, but the barrel pattern is constant, and most riders know what time to expect from their horse for a given arena size. Therefore more barrel horses are examined because of a change or decrease in performance (40%) compared with roping horses (about 25%), rather than overt lameness. In a recent study, 45% of barrel horses that had an owner complaint of running past or wide around the first (right) barrel had a right forelimb musculoskeletal problem.⁶ Unilateral or bilateral forelimb foot pain or subclinical epistaxis was observed in horses that had a recent decrease in speed. Horses that were reluctant to turn to the left had either a left forelimb or hindlimb musculoskeletal problem.

Other musculoskeletal problems depend on the horse's age and level of competition. A young futurity barrel horse may run up the fence, that is, the horse does not turn around the barrel but runs past it up the arena, or it may refuse to enter the arena. No lameness may be detectable, and the veterinarian has to determine whether the young horse is mentally stressed and showing behavioral problems or is responding to pain. Several options are presented to the owner to help determine whether the horse is responding to pain or it is a result of overtraining. One option is to administer phenylbutazone (2.2 mg/kg daily for 2 weeks and then 1.1 mg/kg daily for 2 weeks) for 30 days and to keep the horse in barrel race training. If the horse returns to normal performance, then it is concluded that the horse is most likely experiencing pain. If the problem does not resolve, then I try to address any behavioral problems. If problems persist, I often suggest giving the horse a 3- to 6-month break from barrel racing and have the horse work cattle or perform other less intense activities. A second option is to increase the workload and try to establish whether lameness can be identified and then located with diagnostic analgesia, but few owners select this option. Older, experienced horses usually have pain-related problems.

Most barrel racers train their own horses, and the quality of training is inconsistent, and performance changes may be induced by the rider. Determining which barrel is the problem barrel is helpful. An owner may complain that the horse will not stay in the ground for the first barrel but works fine for the second and third barrels. The horse may perform well for the first barrel but does not make a good turn around the second barrel. The first barrel (usually going to the right) is the hardest barrel and most often a problem because the horse is running at full speed when it reaches the barrel and must slow quickly to make the 360-degree turn. When the horse is turning the barrel, the inside forelimb and hindlimb appear to be under the greatest pressure (Figure 120-6). If the owner complains that the horse is swinging wide or pulling away from the first barrel, the horse does not want to turn to the right and is probably trying to avoid right hindlimb or right forelimb pain.

The teeth are always evaluated to eliminate biting problems as a cause of performance changes.

Fig. 120-6 • A barrel horse turning a barrel. Note the pressure on the inside hindlimb. This horse is on the backside of the barrel coming out of the turn and is in correct position. At this point in the barrel turn, a horse with hindlimb pain becomes uncollected and swings wide around the barrel.

LAMENESS EXAMINATION

A barrel horse does not run at top speed over long distances like flat racehorses; therefore fatigue-type injuries like superficial digital flexor tendonitis or fetlock and carpal chip fractures are seen less commonly than in racehorses. Some of the common injuries seen in barrel horses are attributed to the twisting and turning motion of the horse at high speeds (see [Figure 120-6](#)).

In a recent study, the most common musculoskeletal problem observed in horses used solely for barrel racing was (1) forelimb foot pain (33%), with the right front more often affected; (2) OA of the distal tarsal joints (15%); (3) suspensory branch desmitis or tendon injury (14%); (4) a combination of foot pain and distal tarsal pain (12%); and (5) medial femorotibial joint pain (10%).⁶

If an obvious lameness is not detected when trotting the horse in a straight line or large circle, the horse is trotted in hand in a small circle (1.5- to 3-m radius), mimicking the barrel turn, which will exacerbate the lameness. This may be the only time the horse shows lameness.

DIAGNOSIS AND MANAGEMENT OF SPECIFIC LAMENESS

QHs and Appendix QHs make up most of the barrel horses. Sore feet, navicular area pain, and palmar foot pain are the most frequent causes of forelimb lameness, with poor hoof conformation and farriery and hard arena surfaces being predisposing factors. Diagnosis and management are similar to those described for the team roping horse.

Distal hock OA is the second most common musculoskeletal problem and most common hindlimb problem most resulting in reduced performance or lameness. Diagnosis

is based on intraarticular analgesia, radiology, response to treatment, and sometimes nuclear scintigraphy. The centrodistal and tarsometatarsal joints are treated using methylprednisolone acetate (40 to 60 mg/joint) or triamcinolone acetonide (6 mg/joint) alone or in combination with hyaluronan (10 mg/joint) plus 125 mg of amikacin. Ideally the horse should have 7 to 10 days of turnout or light exercise before returning to barrel racing, but often the competition schedule does not allow this. Response to treatment may take up to 3 weeks. If the horse does not respond to treatment, we reevaluate the horse for lameness.

Hindlimb proximal suspensory desmitis (PSD) and suspensory branch desmitis are common in older, seasoned horses and can be career-ending injuries. Deep sand in arenas may contribute to the high incidence. Moderate lameness (grade 2 to 3 of 5) often is exacerbated by upper limb flexion. The horse usually has no swelling or minimal swelling and no heat and pain for proximal suspensory body lesions, but these will be seen in horses with suspensory branch desmitis. Local analgesia is essential to verify the source of pain. Radiology of the proximal metatarsal area is often negative, although if the condition is chronic, endosteal reaction or enthesioid new bone may be present, seen as increased radiopacity. Ultrasonographic examination may reveal an enlarged and hypoechogenic SL, but some horses have no detectable structural abnormalities. The latter are treated by local infiltration of triamcinolone acetonide (9 to 12 mg) and reduced work. With acute, mild PSD, horses often return to work in 2 to 4 weeks. I also recommend confining the horse to a small area to avoid further damage from excessive uncontrolled exercise. If ultrasonographic abnormalities are detected, the horse is confined to a small area (12- × 30-foot [3.7 × 9.1 m] run) with no riding for 60 to 90 days before reexamination. Complete healing often takes 6 to 12 months, and some horses never return to full athletic function. After the initial 2 weeks of ice therapy, rest, nonsteroidal antiinflammatory drugs, and support bandages, the horse is reevaluated. If the lesion is extensive or severe (type 2 or greater on a scale of 0 to 4), then novel tissue healing therapies such as platelet-rich plasma (PRP) or stem cells are injected into the lesion under ultrasonographic guidance to enhance quality of ligament fiber repair. I have had more experience with PRP and prefer it to stem cell therapy, but both may be beneficial in ligament healing. Hindlimb PSD can be difficult to treat because of the constricting thick fascia surrounding it. If the horse is not sound after 4 to 6 months (depending on severity of lesion) of confinement, then I have had good success performing a fasciotomy and neurectomy of the deep branch of the lateral plantar nerve. Postsurgery care consists of 60 days of stall rest with 20 minutes of daily handwalking and 60 days of controlled exercise program before returning to barrel racing or turnout activity.

PSD is also common in forelimbs. Deep arenas and long toes and low heels are predisposing factors. The prognosis for barrel racing horses with forelimb PSD is good, with most horses responding well to rest and controlled exercise for 3 to 4 months. Tendon protection boots are recommended.

Medial femorotibial joint pain also frequently occurs and is treated in a similar manner as described above for cutting horses (see page 1167). If the lameness is recurrent after several intraarticular injections, diagnostic arthroscopy

is recommended. Metacarpophalangeal joint synovitis results in mild lameness (grade 1 to 2 of 5) that is exacerbated by fetlock flexion. The horse often strongly resists fetlock flexion. Lameness and response to fetlock flexion are eliminated by intraarticular analgesia. Radiology is usually negative. The horse is treated with intraarticularly administered triamcinolone acetonide (6 mg) and hyaluronan (20 mg). The problem may or may not recur. If recurrence is frequent, diagnostic arthroscopy is recommended.

Many times horses have undergone several types of alternative therapies (e.g., equipment changes, acupuncture, chiropractic, and herbal therapy) in an attempt to correct the perceived problems before being checked by a veterinarian. Often, for some inexplicable reason, an accurate diagnosis and conventional medical therapy are sought only after failure of these other treatments. Many owners rely on diagnosis from a fellow competitor and request treatment that was successful in another horse. This makes client communication difficult.

SHOEING CONSIDERATIONS

Traction, especially in the deep and often muddy arenas in which horses compete, is critical. A rim shoe is used most commonly on all feet, with one rim higher than the other to provide added traction. A rounded toe provides easier breakover than a normal flat steel shoe. Hind shoes may have square toes.

Recently the natural balance shoe has gained popularity as owners are becoming more aware of good farriery principles and are trying to correct long-toe, low-heel problems. The natural balance shoe is available in steel or aluminum. Steel construction is preferred because of the added weight, which provides better traction than an aluminum shoe. The natural balance shoe has a rockered toe that eases breakover of the forelimb and is built with a wider web than a normal shoe, which benefits a sore-footed horse competing on hard surfaces.

OTHER CONSIDERATIONS

Exercise-induced pulmonary hemorrhage is common in barrel horses. The owner may complain that the horse has lost a step or has become slower. If a musculoskeletal reason for the performance change cannot be determined, a respiratory evaluation is indicated. Obvious bleeding from the nostrils rarely is seen, but endoscopic examination within 30 minutes of the barrel race often reveals tracheal hemorrhage. Presently no drug testing or rules prevent drug administration for competition. Most horses receive phenylbutazone or flunixin meglumine 4 to 6 hours before competition and furosemide (4 to 8 mL/horse).

▣ THE EUROPEAN WESTERN PERFORMANCE HORSE

Franco Ferrero

The Western performance horse sports have developed in Europe, especially in Germany and Italy, since the mid-1980s, with reining and cutting the most popular sports. Most horses are American Quarter Horses (QHs) and are traditionally broken at 18 months of age. The intense

training needed to show 3-year-olds in the futurity competitions results in many horses not competing at 4 years of age because of behavioral or lameness problems. In an attempt to reduce injuries, there has been a move to shift bigger purses to 4-year-olds. In addition, the Fédération Équestre Internationale (FEI) has recently acknowledged reining as an official discipline, and only horses 6 years of age or older can compete under FEI rules. This is slowly changing the European approach to training of reining QHs.

There is zero tolerance of any drugs in competing horses, and antidoping testing takes place at most official shows in Europe for both professional and nonprofessional classes. This influences the treatment strategies that can be used for lameness. The strict medication rules also influence advice given concerning purchase of horses with pre-existing lameness problems. Increasing attention is being paid to welfare, and strict rules govern which bits and harness are acceptable. Excessive use of spurs or whips may result in suspension of the rider. Common procedures like hair clipping around a horse's nose and ears are not recommended when competing in Germany.

TEN MOST COMMON LAMENESS CONDITIONS IN 2- TO 8-YEAR-OLD EUROPEAN WESTERN PERFORMANCE HORSES

1. Lameness of the foot
2. Lameness of the hock
3. Superficial digital flexor tendonitis
4. Lameness of the stifle
5. Suspensory desmitis
6. Lameness of the metacarpophalangeal/metatarsophalangeal (fetlock) joint
7. Lameness of the carpus
8. Exostoses of the second metacarpal bones (splints)
9. Curb
10. Fracture of the medial plantar process of the middle phalanx

LAMENESS OF THE FOOT

Common causes of foot pain include subsolar abscessation, solar bruising, osteoarthritis (OA) of the distal interphalangeal (DIP) joint, osteitis or fracture of a palmar process of the distal phalanx, and navicular syndrome. Oblique radiographic images of the palmar (plantar) processes of the distal phalanx and a palmaroproximal-palmarodistal oblique image of the navicular bone are particularly valuable.

Poor foot conformation is often an important predisposing factor for the development of foot pain. The foot is often upright with overgrown angles of the wall and heel, flattening of the sole at the toe, and an underdeveloped frog. Bar shoes exacerbate high heel conformation because they prevent the heel bulbs from sinking into the ground; the bar of the shoe concentrates loading and reaction forces from the ground in the bars and underlying structures inducing palmar foot pain.

In such horses trimming of the bars and wall at the heel increases the length of the loading plane, thus distributing ground reaction forces over a wider area. If the horse works on soft ground, reaction forces on the palmar aspect of the foot can be reduced by applying aluminum shoes with

Fig. 120-7 • A typical shoe used in reining horses is made of aluminum and is beveled along the entire outer surface to reduce torsional forces associated with sudden turns and spins.

thinned and beveled heels; if the horse works on harder ground, a complete pad must be inserted between the shoe and the foot, and the shoe must be well concaved on the inner surface to prevent direct pressure to the sole through the pad itself. Shearing forces at the toe can be decreased by moving the breakover point back with a rolled-toe shoe.

Most of the top-level reining QHs are now shod with premade aluminum shoes beveled along the entire outer surface (Figure 120-7; Colleoni/Zaffi design, Farrier Product Distribution, Shelbyville, Kentucky, United States). These are available in either an open or bar type. The beveled outer surface helps the foot to breakover in most of the demanding figures (like spins or roll backs) that produce marked oblique and twisting forces on the distal aspect of the limb. A rocker toe shoe or squared toe is used less frequently because it can restrict the length of the stride.

Treatment of reining horses with navicular syndrome during the show season is challenging because of the long detection times of most commonly used drugs either for local injection or for oral use. Horses with navicular syndrome often have long toe and underrun heel conformation. Treatment involves restoration of a more correct hoof-pastern axis and use of an egg bar or bar shoe to increase the loading area of the foot. A bar shoe also prevents the heel from sinking into the ground and reduces tension on the deep digital flexor tendon. Tendon lesions usually occur toward the insertion. Some are detectable ultrasonographically, but magnetic resonance imaging (MRI) is superior for diagnosis.

The hind feet are subject to enormous loading and twisting forces when horses perform quick stops or when spinning or doing a roll back. Reining horses are shod behind with sliding plates (sliders), which are usually kept long at the heels. A long-heeled shoe concentrates load at the angle of the heel and can create resistance to turning.

LAMENESS OF THE HOCK

Lameness associated with tarsocrural joint is infrequent; however, many veterinarians still inject all three compartments of the hock routinely, thus increasing chances of articular reaction and infection.

Fig. 120-8 • Longitudinal ultrasonographic image of the long digital extensor tendon sheath on the dorsolateral aspect of the hock. Proximal is to the left. There is extensive echogenic material covering the extensor tendon and echogenic bands (arrows) extending between the tendon and the synovium.

OA of the distal hock joints is common. In 2-year-olds there is a high prevalence of partial collapse of the central and third tarsal bones with secondary OA. This is usually accompanied by a camped-under, sickle-hocked, or cow-hocked conformation of one or both hindlimbs.

I use a hock torsion test to try to differentiate pain arising from the centrodistal or tarsometatarsal joints. With the hock in a semiflexed position, I apply a medial to lateral rotational force on the longitudinal axis of proximal aspect of the third metatarsal bone. If the horse reacts quickly or tries to kick, this indicates centrodistal joint pain, whereas if the reaction is slower and the horse gradually lifts and abducts the limb, the test suggests tarsometatarsal joint pain. The hock torsion test is not the “Churchill test.” When performing the torsion test there must be neither direct compression on the medial aspect of the hock nor any compression of the suspensory ligament (SL).

Treatment of horses with OA of the distal hock joints is by intraarticular administration of corticosteroids and sodium hyaluronan. Care must be taken with withdrawal times for horses competing under FEI rules. Horses refractory to intraarticular medication are treated by surgical (drilling) or chemical (sodium monoiodoacetate or ethyl alcohol) arthrodesis. Arthrodesis is most effective in 2-year-olds.

Tenosynovitis of the long digital extensor tendon sheath on the dorsolateral aspect of the tarsus may result in a shortened cranial phase of the hindlimb stride. Ultrasonographic examination of the sheath may reveal tendon lesions and extensive tenosynovial adhesions (Figure 120-8). Treatment involves intrathecal injection of corticosteroids. If chronic, tenoscopic debridement of adhesions and partial retinacular release are indicated.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Acute superficial digital flexor tendonitis is a common cause of lameness in 2-year-old reining and cutting horses. Chronic injuries are seen in older horses that have not received proper treatment of acute lesions. Two groups of

Fig. 120-9 • Transverse ultrasonographic image of the distal metacarpal region of a 3-year-old Quarter Horse filly in full training. Medial is to the left. There is an acute anechogenic lesion of the lateral aspect of the superficial digital flexor tendon, which is swollen.

horses are predisposed to superficial digital flexor tendon (SDFT) injury: (1) young thin-legged Appaloosas, Paints, and QHs with conformation defects such as tied in below the knee, offset knees, and calf knees; and (2) well-built 3-year-old QHs intensely trained, especially working on spins in preparation for the futurity.

Lesions almost invariably affect the most lateral or medial border of the SDFT, usually extending for 3 to 5 cm in the middle or distal third of the metacarpal region, and are seen as diffuse areas of reduced echogenicity (Figure 120-9). Extreme uneven loading of the medial or lateral side of SDFT occurs while the horse is spinning or performing rapid turn backs. To reduce leverage and shearing forces acting on a hoof's quarters in the breakover phase of the spin, top-level reining QHs are currently shod with aluminum shoes beveled along the entire outer surface (see Figure 120-7).

Treatment of horses with acute tendon lesions is aimed at reducing inflammation and edema with rest, cold packs, poultice, stall bandage, oral nonsteroidal antiinflammatory drugs followed by peritendonous injection of low doses of short-acting corticosteroids mixed with antiedema drugs. Intralesional, ultrasound-guided injection of platelet rich plasma (PRP) is performed 10 to 14 days after injury. For acute SDFT lesions in reining or cutting QHs, it is recommended that the horse should not return to full athletic function until at least 8 months after injury.

LAMENESS OF THE STIFLE

Stifle pain is caused by subchondral bone cysts in the medial femoral condyle, traumatic OA, medial collateral ligament injury, osteochondrosis of the femoral trochleas, and fragmentation of the distal aspect of the patella in horses that underwent previous medial patellar desmotomy.

Digital radiography has enhanced the ability to detect subtle alteration in shape of the joint surface of the medial femoral condyle and early changes of subchondral bone opacity in early stages of the disease.

Intraarticular therapy should avoid use of the depot form of corticosteroids because it has been associated with rapid progression of OA and persistent lameness associated with the medial femorotibial joint in reining and cutting QHs. Surgical management of horses with medial femoral condyle cysts using arthroscopically guided injections of methylprednisolone acetate into the cyst lining or curettage results in a 50% to 60% chance for return of the horse to previous level of competition. Rest for 6 to 8 months is mandatory.

SUSPENSORY DESMITIS

Proximal suspensory desmitis (PSD) and desmitis of the branches of the SL are common. PSD affects young reining and cutting QHs in early or advanced training. Lameness is usually intermittent and can vary in intensity from grade 1 to 3 of 5, depending on workload; the horse is lamer with the affected limb on the outside of the circle. Lameness is abolished with analgesia of the lateral palmar nerve. Subtle ultrasonographic changes can be difficult to identify, and comparison with the contralateral limb is useful. Radiology is useful for identification of increased opacity in the proximal aspect of the third metacarpal/metatarsal bone.

Treatment of horses with PSD is based on rest, intralesional injection of PRP, shock wave therapy, radiotherapy/hyperthermia (INDIBA, Sant Cugat del Vallés, Barcelona, Spain). Corrective shoeing comprises an open aluminum shoe wide at the toe and thinned and beveled at the heels. A horse with an uncomplicated PSD lesion requires 90 days of convalescence. The presence of increased bone opacity at the origin of the SL is a poor prognostic indicator, with many horses remaining chronically lame.

Desmitis of a branch of the SL is frequently induced by medial-to-lateral foot imbalance; the wall is lower on the lateral side, and this induces more tensile stress on the lateral branch of the SL. Affected horses often have an offset knee or carpus valgus/fetlock varus and toe-in conformation.

Ultrasonographic examination often reveals hypoechogenic lesions of the most axial part of the branch. Therapy consists of periligamentous injection of corticosteroids and antiedema drugs and intraarticular treatment of the fetlock joint. Horses with chronic branch desmitis are treated with shock wave therapy, hyperthermia, controlled exercise, and repeated local application of working blisters. Shoeing correction involves the use of an open aluminum shoe with wider web on the side of the injured SL branch and balancing the foot.

LAMENESS OF THE FETLOCK JOINT

Osteochondrosis is frequent in front and hind fetlock joints. Most lesions in the dorsal aspect of the joint involve the sagittal ridge of the third metacarpal (McIII) or metatarsal (MtIII) bones, whereas lesions of the palmar (plantar) aspect originate from palmar (plantar) processes of the proximal phalanx.

OA of the fetlock joint is frequently accompanied by insertional desmitis of the SL branches or desmitis of the SL body at the level of its bifurcation. Both the fetlock joint and the SL must be treated for a successful outcome.

Chronic synovitis may result in supracondylar lysis in 2-year-old QHs. Scintigraphy can be useful for identification of increased radiopharmaceutical uptake in the palmar aspect of the condyles of the third metacarpal bone, reflecting bone trauma in horses with no detectable radiological abnormality.

Western performance horses with early fetlock joint OA are managed using serial intraarticular injections with sodium hyaluronan, polysulfated glycosaminoglycans or interleukin-1 receptor antagonist protein (autologous conditioned serum). The prognosis is good. However, if there is thinning of articular cartilage and subchondral bone sclerosis or the presence of cystic lesions in the distal aspect of the condyles of the third metacarpal or metatarsal bones, the prognosis is poor, irrespective of medical or surgical treatment.

LAMENESS OF THE CARPUS

Faulty conformation of the carpi is often present, especially offset knees. Lesions of the carpus include OA of the antebrachio-carpal and middle carpal joints, self-induced trauma of either the accessory carpal bone or the dorsal aspect of the carpus incurred during hard spinning, tenosynovitis of the carpal sheath, chip fractures of the radial or third carpal bones, increased radiopacity (sclerosis) of the radial facet of the third carpal bone, or sagittal fracture.

Sclerosis and sagittal fracture of the third carpal bone are the result of shearing forces caused by uneven loading of the medial aspect of the third carpal bone produced by repeated spinning and galloping in small circles.

EXOSTOSIS OF THE SECOND OR FOURTH METACARPAL/METATARSAL BONES (SPLINTS)

Medial splints are common in 2-year-old reining and cutting QHs, frequently associated with a carpus valgus or offset knee conformation; lateral splints are less common but are occasionally seen in horses with an offset third metacarpal bone and base-narrow conformation.

Splints usually produce transient lameness, but horses with chronic lameness can be managed by freeze firing to reduce local pain and lameness. Shin splints—bony swelling on the proximal dorsomedial aspect of the McII—are occasionally seen in very hard-stopping horses. The swelling is caused by periosteal and endosteal reaction to microfractures produced by repeated compression cycles of the dorsal cortex of the MtIII. Treatment is rest and handwalking for 30 to 45 days and freeze firing to reduce swelling and pain.

CURB

Curb is seen in 2-year-old QHs that have a sickle-hocked/cow-hocked conformation as a result of partial collapse of cuboidal hock bones. Ultrasonographic examination helps to determine which tendonous or ligamentous structure is involved and to decide the appropriate treatment.

FRACTURE OF THE PLANTAR PROCESS OF THE MIDDLE PHALANX

A fracture of the medial plantar process of the middle phalanx is the result of an avulsion caused by extreme pulling of the distal enthesis of the insertion of the SDFT during a stop. The tension in the medial branch of the SDFT may be the result of the wide stance of the hindlimbs that some horses adopt during the last phase of a sliding stop.

Shoeing should aim to correct horses that stop too wide by an inward rotation of the shoe or by applying medial heel extensions (trailers). Surgical management of horses with this middle phalangeal fracture by internal fixation with compression screws has had disappointing results. Prognosis is also poor following digital neurectomy and prolonged rest. Arthrodesis of the proximal interphalangeal joint might be a better choice.

▣ THE RACING QUARTER HORSE

See Chapter 110.

| Chapter 121

Walking Horses

James T. Blackford and James C. Sternberg

DESCRIPTION OF THE SPORT

The Tennessee Walking Horse, commonly called the *Walking Horse*, is a light horse breed developed in middle Tennessee for use on southern plantations during the eighteenth century. The average Walking Horse is 15 to 16 hands tall and weighs 500 to 600 kg. The Tennessee Walking Horse is a composite breed, created by crossbreeding Canadian and Narragansett Pacers and Morgan,

Standardbred, and Thoroughbred horses. The Tennessee Walking Horse Breeders' and Exhibitors' Association was formed in 1935. Because of the versatility of the Walking Horse, along with a characteristic racking gait within the breed, a second breed association was recognized in 1971, the Racking Horse Breeders' Association. Members of this group of horses are commonly referred to as *Racking Horses*.

A Walking Horse performs three gaits: the flat-foot walk, running walk, and canter. Both walks are four-beat gaits, with one foot up and three feet in various phases of striking the ground. The footfall sequence is left hind, left front, right hind, and right front. High-stepping forelimbs with an extended reach characterize the flat-foot walk. The hind foot overreaches the imprint of the front foot by 15 to 55 cm in a straight, smooth, gliding motion. This overstride is unique to the breed and is referred to as the *big lick*. The horse's head and neck nod, and the ears flick forward and backward in rhythmical fashion with the rise

and fall of the front feet. The appearance is that of pulling with the forelimbs and driving or pushing with the hindlimbs. The speed of the flat-foot walk is from 4 to 8 miles per hour (6.4 to 12.8 km per hour). At the running walk, the gait is basically the same but faster (10 to 20 mph [16 to 32 km/h]). The canter is a three-beat gait, with a left or right lead. In the canter the horse lifts the forehand, giving an easy rise and fall, in a rolling motion. The gait is referred to commonly as the *rocking-chair canter* because of the high, rolling movement of the horse's body.

The Racking Horse gait is a bilateral four-beat gait, with one foot striking the ground with the other three limbs in various phases of elevation. The gait often is referred to as the *single-foot gait*. When shown, a Racking Horse performs the show walk, slow rack, and fast rack. The show walk is a smooth, collected, slow and easy four-beat gait. At the slow rack the horse's head is held with the neck arched and ears erect. The fast rack is similar in form to the slow rack, but the horse displays speed and leg action. The natural head nod must not be exaggerated at the slow or fast rack.

In both breeds the collected gaits of a show horse (a gaited horse in performance shoes and tack) shift the center of gravity caudally, compared with most other light breeds, with increased loads on the hindlimbs resulting in a high incidence of hindlimb lameness.

Both breeds are used for show, trail, and pleasure riding. Horses are shown at halter, in harness, and under tack, with English or Western saddles. Horses that are shown wear a light shoe similar to a standard keg shoe, a plantation shoe, or a performance shoe, depending on the class. The plantation shoe cannot exceed 3.8 cm in width and 1.3 cm in thickness, and the heel calk cannot exceed 2.5 cm in height. The performance shoe, or stack, is a shoeing technique used to accentuate the show horse gaits. The shoe is constructed of several layers of flat or wedge pads, stacked one on top of another, placed between a nail pad at the solar margin and a metal shoe on the contact surface. Pads are made of leather, plastic, or hard rubber. The amount of height or extension the shoe provides must not exceed 50% of the natural hoof wall length, measured from the coronary band to the tip of the toe. Pleasure horses are commonly flat shod.

Although the highest population of Walking and Racking Horses is presently in the southeast United States, they are becoming more popular across North America, especially for trail and pleasure riding, because of the physical endurance and gentle disposition of the breeds. The show season generally is considered to be year-round, picking up in the spring and peaking in the fall with the national championships. The Tennessee Walking Horse National Celebration is held in Shelbyville, Tennessee, each year and is an 11-day event ending with the crowning of the national champions on the Saturday before Labor Day. The Racking Horse Celebration is held each year in Decatur, Alabama, during the last 2 weeks in September.

LAMENESS EXAMINATION

Lameness evaluation of a gaited horse is best performed with the horse under complete tack with a rider. It is impossible to duplicate the head set, balance, and shifting of the horse's center of gravity caudally without a rider. The horses generally exercise in a large, oval arena, and to

perform a good evaluation, one needs to provide a place where the horse has room to work in all gaits. The ground surface in this area should be firm. A veterinarian's impression when evaluating a show horse for the first time will be that the horse's problem must be in the forelimb and more specifically the foot. In light of the negative publicity the stacked shoe receives, focusing one's attention on this area is easy. Even as the horse is walked at halter, this impression may not change, because of the awkward nature of the horse handling the bulky shoe. In our experience, few problems are associated directly with the shoe, except hoof wall avulsions, when the shoe is accidentally pulled off in the show ring. Measures to control bleeding must be taken immediately, followed by good wound care. Hoof wall composites then can be used to restore hoof wall function. If an elevated shoe is removed completely and suddenly from an immature, developing horse early in training, removal causes a dynamic mechanical flexural deformity. The horse knuckles over at the fetlock joint because of the pain associated with pulling of the deep and superficial digital flexor tendons.

Unfamiliarity with the standard gaits of Walking and Racking Horses, especially when shod with a stacked shoe, may result in confusion with ataxia, particularly at faster speeds. However, anecdotally, our impression is that a high incidence of cervical vertebral malformation does indeed occur in Tennessee Walking Horses, so this should be kept in mind.

Tennessee Walking Horses are stoic and seem to have a high pain tolerance. Problems encountered in flat-shod Walkers or Rackers mirror the lameness problems seen in other light breeds; therefore the following discussion focuses on show horses in stacked shoes. The hoof tester evaluation is of limited value on the front feet of performance-shod horses. Careful palpation and manipulation of the limbs are performed routinely. Careful evaluation of the foot and shoe should not be overlooked. Use of pressure-shoeing techniques by unscrupulous owners and trainers causes soreness and increases the big lick, conditions that occasionally arise in a performance-shod horse and should not be overlooked. The technique is performed by overtrimming the hoof wall and thus increasing sole pressure. A carefully placed nail in the nail pad encroaching on the sole or the sensitive laminae may be noted. A foreign object, such as a stone inserted between the pad and the sole, inflicts discomfort. Assessment of digital pulse amplitudes, tapping on the hoof wall with hoof testers or a shoeing hammer, and response to nerve blocks may determine the problem.

Problems seen in the forelimbs commonly are associated with imbalances in the shoeing, leading to an uneven height of the forelimb carriage. To evaluate the forelimb carriage, the observer should draw an imaginary line at the chest level, watching the carpal action to determine which leg is carried lower to the imaginary line as the limb advances, indicating the problem limb. When this problem is detected, careful evaluation of the shoeing technique and comparison between limbs are indicated. Correction of foot imbalance may resolve the problem. Osteoarthritis of the distal interphalangeal joint (low ring-bone) frequently is seen in older horses but is not always correlated with lameness. Proximal suspensory desmitis usually is caused by slipping while shod with an elevated

shoe and may be associated with localized pain on palpation. Bicipital bursitis is seen occasionally. The horse may have asymmetry in shoulder motion and pain on palpation of the area, especially when the limb is raised. Abduction or adduction of the shoulder is performed. As in most breeds, sole abscesses are common in flat- or performance-shod horses, as is laminitis.

The highest percentage of lameness seen in our practice with Walking and Racking Horses is associated with the hindlimbs, because of loading of the hindlimbs during exercise. As each hindlimb strikes the ground and the horse's weight is carried through the stride, a rotational, twisting motion also is seen throughout the entire limb before the leg is advanced. This is especially noticeable in the Walking Horse at the faster gaits. The shifting weight and the twisting motion increase stress on the joints and surrounding support structures. Osteoarthritis of the distal hock joints and stifle is common. A positive response to the Churchill test is helpful in isolating pain to the distal hock joints. Careful palpation of the medial patellar ligament is particularly important in this type of sports horse, because at one time almost all of the show horses were subjected to medial patellar desmotomy with hopes of

improving the overreaching stride of the rear legs. Although the medial patellar desmotomy site only occasionally is found to be the origin of the lameness in these horses, the possibility should not be overlooked. The practice is not as common today as in the past; however, many trainers from the old school feel that having the desmotomy performed is important. Upper- and lower-limb flexion tests are performed. Local analgesia is used to define the source of pain. Trochanteric bursitis occurs in Walking and Racking Horses and is related to the rotational, twisting motion of the hindlimbs. The horse has pain on deep palpation over the greater trochanter of the femur, during upper limb flexion tests, and when the hip is stretched forward or backward, abducted or adducted, and rotated.

Other conditions are encountered in these horses. Some have muscular weakness in the hindlimbs, especially young unconditioned horses. When weakness is combined with straight hindlimbs, instability of the patella is common. Chronic hip and stifle soreness caused by a trailer on the outside of the shoe may be an underlying cause of lameness. Osteochondrosis occurs in the forelimbs and hindlimbs. We see a substantial number of horses that are thought to be lame but have equine protozoal myelitis.

Chapter 122

Lameness in the American Saddlebred and Other Trotting Breeds with Collection

Scott D. Bennett

DESCRIPTION OF THE SPORT

The American Saddlebred, Morgan, Hackney Pony, National Show Horse, and Arabian (see Chapter 123) show horses are described as *trotting breeds with collection*. Lameness in disciplines such as dressage, road horses, and road ponies is similar. The American Saddlebred and National Show Horse have five gaits: walk, trot, canter, slow gait, and rack. The slow gait and rack are manmade gaits. These horses also perform in three gaited classes (walk, trot, and canter), fine harness classes, pleasure driving, pleasure-gaited classes, and equitation. Morgan and Arabian horses are shown similarly, but without the slow gait or rack. Hackney ponies are shown in harness, pleasure driving, and road pony classes. Show classes are further divided for professional, amateur, and juvenile riders. Equitation, hunt seat, Western, and numerous young horse and in-hand halter classes are available.

In road horse classes, Standardbreds, Morgans, American Saddlebreds, or Standardbred-cross horses are shown

at the walk, trot, and road gait pulling a bike similar to a sulky used for Standardbred racehorses. These horses usually are more animated in gait than Standardbred racehorses and go both ways around the ring when performing. The road gait is a high-speed performance gait.

To understand lameness in a gaited show horse, the veterinarian must first understand the difference in locomotion between running and gaited horse disciplines. Concussion (impact) is a part of every gait. How a horse distributes concussion is related directly to athletic ability and the longevity of the horse's career. Better equine athletes are more efficient in the distribution of concussion through the limbs and body. A superior equine athlete appears capable of using energy of concussion efficiently and distributing it for dispersion and recovery. Normally kinetic or stored energy from proper distribution of concussion causes recoil of the tissues receiving the energy of concussion. Tissue injury results in an inability to disperse concussive energy properly. Maintaining healthy hoof wall, bone, cartilage, tendons, ligaments, and muscles in a good conditioning and gait management program is essential. A veterinarian must be familiar with the gaits, because gait analysis is an important part of evaluating poor performance and subtle lameness. Many times a veterinarian may be dealing with a gait abnormality caused by the bit, saddle fit, or faulty shoeing rather than lameness.

Gaits of show horses are complex and must be synchronous to maintain distribution of concussion. Synchrony must be achieved in up to five gaits and is altered by the different gait specifications. Unlike most other horses the normal load distribution between forelimbs and hindlimbs in a show horse is about 35% and 65%, respectively (see Chapter 2). A show horse does not have to perform at racing speed. Synchrony of concussion and weight distribution are totally different compared with many sports

horses, and because much concussion is dispersed through the hindlimbs, hindlimb lameness is more prevalent. In some other sports horses the head and neck are raised and lowered with the stride, a movement that assists in balance, energy distribution, and propulsion. A show horse, like a dressage horse, maintains a fixed and flexed head and neck carriage. This further shifts the balance and energy of concussion to the hindlimbs.

Show horses carry more body weight for a fleshier look than the greyhound-like racing counterparts. Riders of show horses, as a rule, also are heavier than racing jockeys.

Longevity of show horses compared with racehorses is related directly to speed of performance, which is dramatically less. Racehorses must change energy distribution at high speed quickly, potentially leading to catastrophic breakdown, but such actions and injuries in show horses are rare. A show horse often can remain competitive into the late teens and early twenties, but chronic wear and tear may result in lameness.

Although show horses do not perform at speed, high head carriage and high limb action and motion are strenuous. Show horses perform numerous gait changes and transitions going in both directions of the ring, and for a high-level (stake class) five-gaited class to last from 30 to 40 minutes is not unusual.

Because five-gaited movements and transitions are complex and arduous, compensatory lameness is common. A methodical approach to lameness diagnosis must be used to differentiate primary and compensatory lameness. A superior show horse distinctly separates its different gait movements, raising each carpus above the horizontal, with a high hock action. The horse drives off its hindlimbs with a flexed high head and neck carriage. Responsiveness to the bit, with an alert expression and attitude, and forward placement of the ears are desirable. Just as racehorses are bred for speed, show horses are bred for animated motion.

AMERICAN SADDLEBRED

The American Saddlebred has a long history and aptitude for different gaits and is derived from many different lineages. The breed was developed in a young country where the best horses could be bred to the best. The American Saddlebred was developed as a horse of usefulness and beauty that could work in the field, pull a buggy or carriage, and have gaits that were smooth for travel under saddle.

The ability of the American Saddlebred to perform lateral gaits (slow gait and rack) came from the Narragansett pacers, which were among the earliest known easy-riding pacers. The Narragansett pacers were derived from French Canadian pacers of Arabian and Andalusian descent that were bred 100 to 200 years before the American Revolutionary War and had a comfortable saddle gait. Early settlers brought these horses, known as *saddlers*, to Kentucky. During the late 1830s and 1840s, many of these easy-riding saddlers were bred to the Thoroughbred foundation sires Denmark and Montrose. These crossbreeds were then bred to horses of trotting blood, from which the Standardbred breed was developed. Offspring of these crosses became favorite mounts of cavalry during the Civil War because they had an easy gait, versatility, and an ability to withstand the pressures of war. On April 7, 1891,

the American Saddlebred Breeders Association was founded in Louisville, Kentucky, and became the first all-American breed registry. In recent years the American Saddlebred has gained popularity in South Africa and has been crossed with European Warmblood and carriage bloodlines (e.g., Dutch Carriage Horse). During the 1980s, the National Show Horse was derived from American Saddlebred and Arabian lineage.

The American Saddlebred ranges in height from 152 to 178 cm (15 to 17.2 hands; average 160 cm [15.3 hands]) and varies in weight from 455 to 545 kg. Colors include chestnut, bay, black, gray, golden (palomino), and spotted (chestnut, black, or bay mixed with white). As described in *Modern Breeds of Livestock*¹:

[The] American Saddlebred has a strikingly long neck and considerable arch to the neck. The American Saddlebred is refined in appearance; has long, sloping pasterns that give spring to the stride; has a long, level croup; is strong and short-coupled; and has a back with high, well-defined withers above the level of the hips. The American Saddlebred is famous for refinement, smoothness, proportion, and a beautiful and handsome presentation and projects an alert, curious, expressive personality.

There are shows for American Saddlebreds throughout the United States and South Africa. The World Championship Horse Show is held each year in Louisville, Kentucky. Shows are run under the guidelines of USA Equestrian, which establishes rules, regulations, and drug-testing procedures. A veterinarian must be aware of current drug and medication rules, and failure to do so may result in fines and penalties to the horse, owner, and trainer.

SADDLEBRED GAITS

The five gaits of the American Saddlebred and other gaited horses are as follows²:

1. *Walk and flat walk*—The flat walk is a relaxed, elastic, ground-covering, and collected four-beat gait, maintaining proper form and consistency in stride. The gait is required in pleasure classes. The animated walk is a highly collected gait, exhibiting much primp at a slow, regulated speed, with good action and animation. The gait can be a two- or four-beat gait and is performed with great style, elegance, and airiness of motion.
2. *Trot*—The trot is a natural, diagonal two-beat gait. A balanced trot features coordinated motion with straight, true shoulder motion of forelimbs, with flexing hocks carried close together. The gait is executed in a highly collected manner and should display the horse's athletic ability.
3. *Slow gait*—The slow gait was developed from the pace to be a four-beat gait with each of the feet striking the ground separately. In the takeoff the ipsilateral front foot and hind foot start almost together, but the hind foot contacts the ground first. The slow gait is a highly collected gait, with most of the propulsion coming from the hindquarters, whereas the forequarters assist in the pull of the final beats. The slow gait is not a medium rack. The slow gait is a restrained gait, executed slowly, but with true and distinct precision, and speed is penalized. The gait is

high, lofty, brilliant, and restrained, denoting the style, grace, and polish of the horse.

4. *Rack*—The rack is a four-beat gait in which each foot meets the ground at equal, separate intervals. The gait is smooth and highly animated, performed with great action and speed in a slightly unrestrained manner. Desired speed and collection are determined by the maximum rate at which a horse can rack in form. Racking in form should include the horse remaining with a good set head and should be performed by the horse in an effortless manner from the slow gait, at which point all strides become equally rapid and regular. Any tendency to become trotty, pacey, or hitchy-gaited is penalized.
5. *Canter*—The canter is slow, lofty, and fluid, with a definite three-beat cadence. High action, a good way of going, and proper collection are paramount. The propulsion is in the hindquarters, with the leading forelimb sustaining the concussion of the final third beat. A brief interval occurs when all feet are off the ground. The gait is an ambidextrous gait, executed on the lead that is toward the center of the ring to relieve stress and aid in balance.

LAMENESS EXAMINATION

The history of lameness and poor performance must be discussed with the trainer and rider to seek their perception. This should include noting any problems with the bridle and the way a horse pulls on the bit and bridle. Show horses with hindlimb lameness often fight the bit and try to lower the head, an observation known as *diving in the bit*. Horses that become one-sided in the bit may have contralateral hindlimb or ipsilateral forelimb lameness. Faulty bit and bridle placement may cause gait abnormalities, particularly of the hindlimbs. Keeping the head up and fixed in position in a horse that dives in the bit is difficult. A horse with forelimb lameness is more likely to raise up out of the bridle. A horse cannot produce a gait properly or do proper gait transitions when being pushed into an uncomfortable bridle or if the rider is using the bit improperly. It is important to determine if the rider is using the bit to balance the horse or himself or herself. A rider using the bit poorly can induce a gait abnormality. Bit and bridle responsiveness is often a wild card that must be played during examination of a show horse for gait abnormalities and lameness.

Problems with a particular gait may indicate the source of lameness. Back pain is seen in horses that have difficulty in the canter, a condition known as *being broke in the middle*. This occurs with asynchronous movement of the forelimbs and hindlimbs. Broke in the middle also can be caused by stifle pain that causes a reduction in the cranial phase of the stride. Most commonly, however, broke in the middle is caused by stringhalt. Stringhalt prevents the limb from moving forward at a time when the forelimbs are required to go faster, causing a mismatch in synchronization between the forelimbs and hindlimbs. Distal hock joint pain and back pain can cause a hitching motion of the hindlimbs, jerking the lame limb caudally and leaving the hocks behind the motion.

Examination first begins in a stall before the horse is worked. Careful palpation with emphasis on the tendons,

ligaments, joint capsules, and bulbs of the heels should be performed. Palpation of the back and gluteal muscles before working is important, because the horse can warm out of soreness in these areas. Digital pulse amplitudes should be assessed.

The horse should be evaluated during movement under tack. Harness horses, road horses, and ponies should be examined while working with and without the overcheck (checked up and without the check). Five- and three-gaited horses should be examined performing each gait going in both directions. Often horses are lame only while going in one direction or only in the turns. Horses with lameness from the hock distally are often worse with the lame limb on the inside, whereas those with pain located more proximally are lame with the lame limb on the outside of the turn. Forelimb lameness is usually worse with the affected limb on the inside.

In most show horses flexion tests can be performed with a rider or in harness. The horse's temperament may make this difficult, but I find that the horse being ridden or jogged in a cart after flexion is helpful.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia in show horses is similar to that described for other sports horses. I start distally and work proximally.

IMAGING CONSIDERATIONS

Conventional and computed or digital radiography are used extensively. Scintigraphy is most useful in horses with complex lameness, because primary and compensatory issues are difficult to differentiate. The solar scintigraphic image is mandatory to evaluate horses with palmar foot pain in which radiographs are negative, and may reveal evidence of abnormal modeling of either the navicular bone or the distal phalanx. Areas of increased radiopharmaceutical uptake in the distal phalanx may indicate excessive pressure that can be relieved by corrective shoeing. Thermography is of value in diagnosing tendonitis, sole pressure, muscle inflammation, and suspensory desmitis. Ultrasonographic examination is useful to confirm and assess damaged soft tissues and healing. Diagnostic arthroscopy is used occasionally.

Magnetic resonance imaging (MRI) has added hugely to the ability to diagnose and differentiate difficult lameness problems. Evaluation of the soft tissues, ligaments, and tendons of the feet, fetlocks, hocks, carpus, and stifles has created a quantum leap in the ability to diagnose bone, cartilage, and soft tissue injury.

SHOEING GAITED HORSES

Shoeing gaited horses to assist with motion and gait transitions is an art form in itself. In general a long toe and high heel in front help to delay breakover and cause high knee action. In the past, weighted shoes and lead weights screwed into the bottom of shoe pads were used to induce animation. In recent years a transition to "lighter is better" has occurred, and now the focus is on fitness and training techniques to teach a horse to elevate its limbs to achieve animation. Shoeing depends to a great extent on a horse's

ability, conformation, and desired gait performance (e.g., five-gaited, three-gaited, or harness). For example, a three-gaited horse may have a long foot with long toe and heel length to delay breakover in the forefeet and hindfeet. This gives the extreme highly animated knee and hock action expected from a top three-gaited horse. In contrast, in a five-gaited horse a lower hind heel angle is used to assist with a longer hindlimb stride needed for the slow gait and rack. Compared with three-gaited horses, lighter and shorter front feet are maintained in five-gaited horses to promote speed at the trot and rack.

Shoeing with high heels and long toes, with or without pads, predisposes the American Saddlebred to a contracted heel, sheared heel, and quarter cracks. The recent use of cushion polymer compounds to maintain frog pressure is helpful, because frog pressure is lost with high heels and pads. Cushioned polymers placed in the collateral sulci (grooves) of the heel and over an atrophied frog have dramatically reduced hoof problems. Medial-to-lateral hoof balance is paramount.

TEN MOST COMMON LAMENESS CONDITIONS

The 10 most common lameness conditions in show horses are the following:

1. Distal hock joint pain (tarsitis)
2. Gluteal myositis and back pain
3. Palmar foot pain, including contracted heel, sheared heel, quarter cracks, navicular syndrome, tears of the deep digital flexor tendon, and injury of the distal sesamoidian impar ligament
4. Osteitis of the distal phalanx (pedal osteitis)
5. Osteoarthritis and osteochondrosis of the tarsocrural joint
6. Osteoarthritis and osteochondrosis of the fetlock joint
7. Osteoarthritis and osteochondrosis of the stifle joint
8. Suspensory desmitis
9. Tendonitis and desmitis, including deep digital flexor tendonitis, superficial digital flexor tendonitis, and desmitis of the accessory ligament of the deep digital flexor tendon
10. Splint exostosis

SPECIFIC LAMENESS CONDITIONS

Distal Hock Joint Pain and Distal Tarsitis

There are two types of show horses: those that have distal hock joint pain and those that are getting it. Show horses with distal hock joint pain typically jerk the hindlimb caudally (hitching) and leave the hocks behind in motion. Many horses stab the toe, rather than landing normally with the heel first.

Distal hock joint pain without radiological abnormality is common in 2- and early 3-year-olds just starting to rack. As training and showing proceed, radiological evidence of osteoarthritis (OA), such as loss of joint space and periarthritic osteophytes, can become apparent as early as 5 years of age and may be severe by 12 years of age.

The tarsometatarsal joint is by far the most valuable point of intraarticular injection in show horses. Occasionally, injection of the centrodistal (distal intertarsal) joint also is required. I prefer to use hyaluronan and a low-dose

corticosteroid combination and recommend oral supplementation with glucosamine and chondroitin sulfate-containing products. Magnetic therapy appears beneficial in horses with early onset of pathology. Horses with lameness that does not improve are considered candidates for shock wave therapy and/or treatment with interleukin-1 receptor antagonist protein (IRAP). Arthrodesis of the distal hock joints, using a drilling technique combined with laser ablation, is recommended in horses with severe pain or evidence of osteonecrosis of the distal tarsal bones detected radiologically or possibly earlier using MRI.

Although cunean tenectomy was once widely used, effects of the procedure are short-lived, and I do not recommend it. If a horse is hitching through the turns of a show ring, a 45° flat outside trailer is used on the hind shoe for support. The shoe is set back, and the toe is squared or rolled to improve breakover.

Gluteal Myositis and Back Pain

Show horses are prone to gluteal myositis and back pain, which are often secondary to primary distal hock joint pain. A willing horse hyperflexes its back to compensate for lower hindlimb pain. The middle gluteal muscle passes over the greater trochanter of the femur and the trochanteric bursa. Gluteal myositis and tendonitis are common sequelae to distal limb pain, but they can cause primary lameness. Trochanteric bursitis (whorl bone disease) can accompany gluteal myositis.

In horses with subacute gluteal myositis, upper limb flexion may stretch the gluteal muscles and produce a transient improvement in gait. Transient improvement may be seen by gently massaging the greater trochanter and gluteal muscles. However, in horses with chronic myositis with involvement of the trochanteric bursa, deep massage and pressure may make lameness worse. Horses with subacute primary gluteal myositis commonly have a tightrope trot (plaiting). Plaiting is associated with distraction and rotation of the hindlimb, with subsequent lateral movement of the hip, motion that may cause gluteal muscle strain. Horses that plait usually have base-narrow conformation, and corrective trimming in the form of spreading the stance (lowering the outside hoof walls) may help.

Back pain is identified easily using digital pressure along the thoracolumbar region, abaxial to the spinous processes. Many horses are in so much pain that one can almost put them on the ground with digital pressure. Diagnostic analgesia usually is not necessary. However, small amounts of local anesthetic solution injected at numerous sites along the affected muscles may give enough relief to allow evaluation for lameness that has been hidden by back or gluteal pain.

Management of horses with gluteal myositis and back pain requires a multifaceted approach, including local injection of Sarapin and corticosteroids. In most horses nonsteroidal antiinflammatory drugs (NSAIDs), methocarbamol, electrical stimulation, magnetic therapy, therapeutic ultrasound, and anticoncussion saddle pads are used in various combinations. Exercise regimens using stretching and flexing during the warm-up period are also beneficial. Acupuncture and chiropractic modalities often are used and can be of benefit if performed by skilled practitioners. Extracorporeal shock wave therapy (ESWT), with or without intramuscular injection of a combination of

Sarapin, dimethyl sulfoxide (DMSO), and a low dose corticosteroid, is effective for immediate relief. Diagnosis and treatment of primary lameness problems, if present, are of utmost importance.

Palmar Foot Pain

Because show horses are shod intentionally with a high heel and long toe to produce high motion, they are prone to a contracted and/or sheared heel. Full or wedge pads are often applied to achieve the desired motion, and the lack of frog pressure can cause atrophy of the soft tissues of the heel. Without proper frog support, the bulbs of the heel contract and a sheared heel often develops. As the heel contracts or a sheared heel develops, more stress is applied to the quarters, predisposing the hooves to quarter cracks. Differentiation of causes of palmar foot pain is critical but difficult, because palmar digital analgesia affects these conditions and navicular syndrome similarly.

Recently more concern has arisen about maintaining frog pressure. Soft, acrylic polymers are now used for frog support in horses with frog atrophy. Turnout for several months, during which the horse is barefoot, may help. Expansion springs can be used to assist in reestablishing proper heel conformation. Severe quarter cracks are repaired using a lacing technique, applying screw compression plates, or nailing. Floating the heel bulb and quarter located under the crack is important to reduce weight bearing, allowing showing to continue.

Navicular disease is not uncommon, but in horses without abnormal radiological findings the diagnosis should be confirmed using scintigraphy. The aforementioned conditions of the hoof capsule and supporting soft tissues are much more common.

Treatment of soft tissue causes of palmar foot pain involves maintaining comfort while proper anatomy is reestablished. Corrective shoeing, NSAIDs, and long-term foot blocks often are used. If navicular disease is confirmed, intraarticular treatment of the distal interphalangeal (DIP) joint using hyaluronan and corticosteroids is recommended. Drugs aimed at improving peripheral perfusion or decreasing intraosseous pressure such as isoxsuprine may be useful with NSAIDs, long-term foot blocks, and corrective shoeing. ESWT appears promising in managing palmar foot pain.

MRI has been particularly beneficial for differentiating navicular disease, navicular bone cystic disease, deep digital flexor (DDF) tendonitis (see Chapter 32), adhesions of the DDF tendon (DDFT), distal sesamoidean impar desmitis, cartilage defects of the DIP joint, disruptions of the laminae and hoof capsule, and hemorrhage or abscessation of the structures of the foot. Blood flow studies using MRI contrast techniques are invaluable for evaluation of circulatory disturbances of the foot.

Osteitis of the Distal Phalanx

In horses with high stepping gaits the distal phalanx is prone to injury. Trauma to the solar margin such as bruising and fracture occurs. A careful evaluation for improper sole pressure or medial-to-lateral hoof imbalance should be performed. Well-exposed and well-positioned radiographs are essential. Digital venography may reveal compression of blood vessels within the hoof capsule and is useful to pinpoint a location of trauma.

Fig. 122-1 • Sagittal T1-weighted magnetic resonance contrast venogram in a normal horse, produced using three-dimensional reconstruction after soft tissue and bone subtraction techniques were applied.

Fractures of the distal phalanx are rare. Solar scintigraphic images are useful to diagnose fractures and other areas of distal phalangeal trauma and can help to formulate a corrective shoeing plan. Thermography may be useful for diagnosis of distal phalanx trauma.

For horses without distal phalangeal fracture, management includes corrective balancing and shoeing to relieve improper sole pressure and to provide support, NSAIDs, and isoxsuprine. If effusion of the DIP joint is present, intraarticular treatment with hyaluronan and corticosteroids, or IRAP is beneficial.

MRI of the distal phalanx may identify evidence of bone contusions. MRI blood flow contrast studies are more accurate than standing venograms and a computerized three-dimensional rotation can be accomplished with soft tissue and bone subtraction (Figure 122-1).

Osteoarthritis and Osteochondrosis of the Tarsocrural Joint

Lameness of the tarsocrural joint is not as common as distal hock joint pain. Osteochondrosis of the tarsocrural joint in show horses is similar to that described for other sports horses. The most common location is the cranial aspect of the intermediate ridge of the tibia. Although show horses with osteochondrosis lesions may compete successfully without surgical intervention, effusion and capsulitis are indications that surgery should be performed. Prognosis after arthroscopic surgery is favorable. However, prognosis for show horses with osteochondrosis lesions of the trochlear ridges of the talus is guarded. Osteophytes and small fragments of the distal aspect of the medial trochlear ridge are not a major source of lameness.

The diagnosis of OA of the tarsocrural joint is derived from the results of physical examination, flexion tests, diagnostic analgesia, radiography, nuclear scintigraphy, and MRI. Horses with early OA of the tarsocrural joint are managed with intraarticular injections of hyaluronan, with or without corticosteroids. Oral supplementation with glucosamine and chondroitin sulfate-containing compounds appears beneficial. Intramuscular and intravenous

administration of polysulfated glycosaminoglycans and hyaluronan, respectively, are helpful. NSAIDs may be necessary. Horses with chronically distended tarsocrural joints (so-called boggy hocks) usually respond well to routine intraarticular medications, but if they are refractory, I add 0.5 mL atropine sulfate. IRAP appears effective for management of horses with chronic capsulitis and OA of the tarsocrural joint.

MRI of the tarsocrural joint and distal aspect of the tibia has permitted identification of soft tissue damage, tibial stress fractures, and bone cysts communicating with the tarsocrural joint, which may be associated with damage to the opposing cartilage and subchondral bone.

Osteoarthritis and Osteochondrosis of the Fetlock Joint

Conditions of the fetlock joint in show horses are essentially the same as seen in other sports horses. The most common conditions are osteochondral fragments of the proximal dorsal aspect of the proximal phalanx and sesamoiditis. Plantar process osteochondrosis fragments are uncommon but are recognized. During prepurchase examinations, I obtain lateromedial radiographic images of each metatarsophalangeal joint specifically to evaluate for plantar process fragments. Fractures of the proximal sesamoid bones occur infrequently. Osseous cystlike lesions of the distal aspect of the third metacarpal bone (McIII) and osteochondritis dissecans (OCD) lesions of the sagittal ridge of the McIII occur infrequently and are less devastating than in racing breeds. Mineralized proliferative synovitis lesions are often confused with osteochondral fragments, but show horses with this condition have a favorable prognosis. Primary OA of the fetlock joint is seen commonly in show horses that wing the lower limb while moving, but radiographs are often negative.

Diagnosis of lameness of the fetlock joint is routine, using radiography, nuclear scintigraphy, ultrasonography, and, when necessary, MRI. Nuclear scintigraphy is most useful in diagnosing sesamoiditis.

Arthroscopic removal of osteochondral fragments of the proximal phalanx is not always necessary, because many show horses compete well and require little maintenance therapy when fragments involve the front fetlock joints. When fragments involve the hind fetlock joints, arthroscopic removal is recommended, because these horses have gait abnormalities characterized by a skipping motion that are accentuated at the rack and slow gait. This is particularly evident in horses with plantar process fragments of the proximal phalanx.

Horses with sesamoiditis respond well to corrective shoeing (lowering the heel), NSAIDs, isoxsuprine, and injection of hyaluronan and corticosteroids into the fetlock joint. Shock wave therapy appears to be effective in managing horses with chronic sesamoiditis, collateral ligament damage, and severe arthritic changes. Treatment with IRAP with or without ESWT is beneficial in horses with severe OA.

MRI may be helpful for evaluation of the articular cartilage and subchondral bone and for identification of injuries of the intersesamoidean ligament (Figure 122-2), oblique sesamoidean ligaments, straight sesamoidean ligament, palmar annular ligament, and digital flexor tendons.

Fig. 122-2 • Transverse high-resolution spin echo magnetic resonance image of a metacarpophalangeal joint (dorsal is to the top and lateral to the left) showing an area of increased signal intensity (arrow) in the intersesamoidean ligament. This lesion was debrided arthroscopically.

Osteoarthritis and Osteochondrosis of the Stifle Joint

OA of the stifle joints is a common lameness in show horses, particularly in horses being pushed to perform at a young age. Normal weight distribution favoring the hindlimbs, coupled with learning the slow gait and rack at a young age, predispose the horses to stifle pain. Horses with stifle lameness usually have a shortened cranial phase of the stride and are said to be “humping up in the hip” at the beginning of the caudal phase of the stride. Lameness often is pronounced with the limb on the outside of the ring and is worse in the turns. Diagnosis is made using assessment of gait, diagnostic analgesia, radiography, nuclear scintigraphy, and MRI if needed. Subchondral bone cysts of the medial femoral condyle and OCD of the trochlear ridges of the femur are commonly diagnosed in young show horses with stifle effusion. Arthroscopic surgery, debridement, and fragment removal are recommended in those horses with effusion and lameness. Prognosis for a five-gaited horse with OCD of the stifle is guarded, even with surgery. Many of these horses can compete successfully in other divisions such as harness, pleasure driving, and equitation.

Distal patellar fragmentation and cartilage damage are seen in older horses, and horses respond well to intraarticular injections of hyaluronan and corticosteroids. Arthroscopic surgery is recommended in horses refractory to this therapy.

Lateral luxation of the patella occasionally is diagnosed in foals, which have a guarded prognosis. Atrophy of the trochlear groove of the femur usually occurs with this condition, which may be genetic and familial.

Upward fixation of the patella is seen in young horses with underdeveloped quadriceps muscles. Most improve with training in a jog cart to build up the hindlimb musculature in lieu of intense riding and training. Trainers must be advised to be patient. Medial patellar desmotomy should be used as a last resort and should be done only if radiographs of the stifle are negative. Horses with early OA

Fig. 122-3 • Dorsal turbo spin echo magnetic resonance image of a stifle joint (proximal is to the top and medial is to the left) in a show horse showing an area of low signal intensity consistent with bone injury of the distal aspect of the medial femoral condyle (*upper arrow*) and corresponding mild injury of the proximal medial aspect of the tibia (*lower arrow*). The medial meniscus (*left arrow*) is shaped abnormally.

and negative radiographs are managed by decreasing training intensity and implementing a jogging program to develop the hindlimb musculature. A weighted drag behind the cart is added later, before the normal riding program resumes. Internal blisters are used commonly. Intraarticular injection of hyaluronan and corticosteroids alleviates clinical signs, but without modification of exercise the results are short-lived.

Horses with chronic OA are maintained using intraarticular injections, oral supplements, intramuscularly and intravenously administered polysulfated glycosaminoglycans, and NSAIDs.

MRI may reveal degeneration of the meniscal cartilages in areas of contact with osseous cystlike lesions of the proximal aspect of the tibia or subchondral bone cysts in the medial femoral condyle. Identification of injury of the meniscal cartilages, meniscotibial ligaments, and cruciate ligaments is important for establishing a prognosis and formulating a management plan in show horses with stifle joint disease (Figure 122-3).

Suspensory Desmitis

Show horses with long pasterns and high heels are prone to suspensory desmitis because the fetlock drops excessively and stretches the suspensory ligament. Show horses trained in deep footing (sand or mud) are at increased risk for suspensory desmitis. Avulsion fracture of the McIII at the origin of the suspensory ligament may occur in association with suspensory desmitis. Suspensory desmitis is more common in forelimbs than in hindlimbs. Treatment of show horses with suspensory desmitis involves rest, NSAIDs, periligamentous injection of corticosteroids, leg sweating, magnetic therapy, and support wraps. Rest includes handwalking, because horses with suspensory desmitis appear to respond better to limited, controlled exercise than to stall rest alone. The heel should be lowered and a palmar or plantar extension applied.

ESWT has been extremely beneficial in show horses with suspensory body or suspensory branch injuries, and particularly those with proximal suspensory desmitis. Intralesional injection with IRAP or stem cells, combined with ESWT, has been most effective.

MRI may give additional information about suspensory pathology compared with ultrasonography, permitting identification of adhesions to the second or fourth metacarpal (metatarsal) bones.

Tendonitis

Performing in deep, muddy, outdoor show rings and a long-toe, high-heel hoof conformation predispose horses to tendonitis of the superficial digital flexor tendon (SDFT) and DDFT and desmitis of the accessory ligament of the DDFT. As a rule tendonitis is not nearly as devastating in show horses as in racehorses.

Horses with tendonitis respond well to sweats, peritendinous injection of corticosteroids, NSAIDs, magnetic therapy, and ESWT. Rarely, show horses require tendon splitting and desmotomy of the accessory ligament of the DDFT or the accessory ligament of the SDFT. Serial ultrasonographic examinations are important to monitor healing.

Splint Exostoses

Splint exostoses are caused by lunging young horses in tight circles too fast and too long. Direct trauma from interference can cause splint exostosis or fracture. Once splints become inactive, they rarely cause lameness, unless the mineralization impinges on the suspensory ligament or if the exostosis is so large that it repeatedly becomes traumatized. Diagnosis is made by palpation and radiological assessment for fracture. Treatment consists of leg sweats, subcutaneous injections of corticosteroids over the exostosis, and ESWT in horses refractory to sweating and injections. Surgical removal of distal splint bone fracture fragments, large exostoses, or nonunions that impinge on the suspensory ligament should be performed.

OTHER LAMENESS CONDITIONS

Stringhalt

Stringhalt is common in the show horse and needs to be differentiated from other hindlimb lameness conditions. Local anesthetic solution (5 mL at each of three sites) is injected into the lateral digital extensor muscle, and the horse is observed while ridden 10 minutes later. If gait is improved, I recommend lateral digital myotomectomy. Previous trauma to the lateral or common digital extensor tendons can predispose horses to stringhalt (see Chapter 48).

Semimembranosus or Semitendinosus Myositis

Myositis of the semimembranosus or semitendinosus sometimes can mimic stringhalt and cause bizarre gait abnormalities similar to fibrotic myopathy. Horses and ponies (particularly road ponies) show restriction of the cranial phase of the stride. The hindlimb appears to hang up in a flexed position, or the horse is short-strided. Typically a trainer says the horse cannot get underneath itself. This occurs particularly in gaited horses that cannot perform the slow gait or rack. This condition may be an early form of fibrotic myopathy.

Diagnosis involves injecting 5 mL of local anesthetic solution in three or four sites each in the semimembranosus and semitendinosus muscles. The horse is evaluated ridden in 10 minutes, and often the change is dramatic.

Short-lived benefit is seen by injecting the involved muscles with Sarapin and a corticosteroid and using electrotherapy. The best solution appears to be tenotomy of the medial branch of the semitendinosus muscle, the same procedure described for surgical management of horses with fibrotic myopathy.

Tibial Stress Fractures

Young show horses, particularly young, talented five-gaited prospects, can become suddenly difficult to gait. Typically the trainer says, "The horse was one of the best young prospects I ever had, and then suddenly I lost him," or "Everything came undone." Tibial stress fractures are the show horse counterpart to bucked shins in the Thoroughbred. Diagnosis is difficult and usually involves ruling out everything else first and proceeding to nuclear scintigraphy, the most consistent and best method of diagnosis. Horses are given 60 days of jogging and are reassessed.

Hindlimb Extensor Tenosynovitis

The long digital extensor tendon sheath at the level of the hock can become inflamed and distended, a condition that is particularly prevalent in talented gaited horses. There is usually an indentation of the distended sheath just below the hock, caused by constriction by the retinaculum.

Although lameness is unusual, severe distention of the sheath may cause a stiff gait, because the horse cannot flex the hock normally. Tenosynovitis may be confused with bog spavin. If left untreated, the synovium becomes hypertrophic, and movement of synovium under constricting retinaculum causes a hitch in hindlimb gait. Treatment consists of draining synovial fluid and injecting a combination of hyaluronan, corticosteroids, and 0.5 mL of atropine sulfate. Massaging with DMSO and a corticosteroid is also beneficial.

Cervical Myositis

The degree of neck flexion required in show horses often causes pain, particularly in young horses. Older horses may develop OA of the facet joints, especially of the fifth to seventh cervical vertebrae. Diagnosis is based on radiological examination and nuclear scintigraphy. Myelography may be necessary if there is evidence of hindlimb incoordination. Horses with cervical myositis and pain often are observed to be fighting the bit. Diagnosis is made by palpation. Injection of Sarapin and corticosteroids in the affected muscles, methocarbamol, electrical stimulation, and NSAIDs are used. Acupuncture and chiropractic procedures also may be beneficial. ESWT may be beneficial in horses with OA of the facet joints. Ultrasound-guided intraarticular injection may also be of benefit.

Chapter 123

Lameness in the Arabian and Half-Arabian Show Horse

Jeffrey A. Williams and Bradley S. Root

HISTORY OF THE ARABIAN

The Arabian is one of the oldest breeds in the world. The horse originated in the deserts of the Middle East and was used by the Bedouins for transportation and in battle. The Arabian breed was noted for its speed and endurance. Three Arabian stallions (the Godolphin Barb, Byerley Turk, and Darley Arabian) imported to Europe during the late 1600s and early 1700s became the foundation of a new breed of horse, the Thoroughbred. Today, 93% of all modern Thoroughbreds can be traced to these three sires. In the 1800s many royal families of Europe established Arabian stud farms. Two of the most notable were the Polish National Arabian Stud in Poland and the Crabbet Arabian Stud in England. The Arabian is thought to have an influence on many of the light horse breeds that have developed throughout history. A typical Arabian ranges from 14.1 to 15.1 hands in height. The American Horse Show Association breed standards describe the Arabian as having a

small, slightly dished face with large eyes set well apart, small ears, deep and wide jowls, a small muzzle, and large nostrils. The horse should have a long, arched neck; a long, sloping shoulder; well-sprung ribs; a short back with a relatively horizontal croup; and natural, high tail carriage. The limbs should have large, well-defined joints, short cannon bones, sloping pasterns of good length, and round feet of proportionate size.¹

The Half-Arabian studbook originated with the United States Army Remount Service after World War II and was acquired by the International Arabian Horse Association in 1951. Half-Arabians must have a registered purebred Arabian sire or dam. The Anglo-Arabian is a cross between an Arabian and a Thoroughbred, whereas the more recently developed National Show Horse is a cross between an Arabian and a Saddlebred. Many Half-Arabians are double registered.

HISTORY OF THE SPORTING EVENT

The International Arabian Horse Association was created in 1950 to join the local and regional clubs across America into one united association. The International Arabian Horse Association promotes and coordinates all Arabian and Half-Arabian horse show activities and develops horse show rules. The International Arabian Horse Association also maintains the Half-Arabian and Anglo-Arabian registries, whereas the Arabian Horse Registry of America maintains the registry and pedigree records for purebred Arabian horses in the United States and Mexico.

The first United States National Arabian and Half-Arabian Show was held in 1966. The United States National

Show is held in October in Tulsa, Oklahoma. A separate Youth National show for riders under 18 years old is held in July of each year in Albuquerque. The Canadian National Horse Show is held in August in Regina, Saskatchewan. The Sport Horse Nations, an event for Arabians and Half-Arabians competing in dressage, working hunter-jumper, and carriage-driving categories, is held at a different time and location each year. The United States and Canada are separated into 18 regions, each of which holds an annual show. Horses can qualify for the national show by placing in the top five at a regional show or by accumulating points at Class A shows. Some of the major shows in the United States other than the regionals and nationals are the Scottsdale Show (Arizona), the Buckeye Show (Ohio), the Pacific Slopes Show (California), the East Coast Championship (Pennsylvania), and the Pro-Am Challenge (Texas). Major international shows are held in England, France, South America, and Australia.

Performance classes for Arabian and Half-Arabian horses cover a broad spectrum and are listed in [Box 123-1](#). Each of these classes is held separately for Arabians and Half-Arabians. They may be divided further into sections for junior owner, adult amateur owner, amateur owner, junior exhibitor, and amateur. The Park horse has a strong animated trot, with the forearm horizontal and the limb extending fully forward. The hock has a well-raised driving action. The walk and canter are animated and collected. The English Pleasure horse is shown at a walk, trot, strong trot (faster and more animated than the normal trot), canter, and hand gallop. Its gaits are less animated than those of the Park horse, although the forearm, at the trot, is horizontal. The same gaits are used in the Country English Pleasure class, but horses have lower limb action,

and high action is penalized. The Country English Pleasure horse must also halt, stand quietly, back, and walk off on a loose rein. With all pleasure classes the horse must give the appearance of being a pleasure to ride. Park horses and English Pleasure horses are shown with the head carried high and considerable flexion at the poll. Saddle seat attire is required.

In the English Show Hack class a horse must perform each gait (walk, trot, and canter) in a normal, collected, and extended manner. A transition between gaits should be noticeable, and high knee action is not expected. Horses in the Hunter Pleasure division are shown under saddle at the walk, trot, canter, and hand gallop. The neck should be carried lower, the head should be carried with less bend at the poll, and the horse should be in a generally longer frame than the English Pleasure or Show Hack horse. Working Hunters are shown over a course of fences set at levels of 0.6 to 1 m and are judged on performance, manners, and soundness. Jumpers are shown over courses of jumps that vary in height from 0.9 to 1.05 m. The maximum width (spread) is 1.5 m.

Horses in driving classes are shown pulling a four-wheeled (Formal and Pleasure) or two-wheeled (Pleasure and Country Pleasure) vehicle. The gaits judged in the Formal, Pleasure, and Country Pleasure driving classes correspond to the Park, English Pleasure, and Country English Pleasure classes under saddle. The Roadster is a driving class that focuses on the trot at three different speeds.

The Western Pleasure horse is shown at the walk, jog (trot), lope (slow canter), and hand gallop. Ideally, contact with the reins is light, the head is carried low (approximately at the level of the withers), and the jog and lope are slow, easy gaits. The Working Western horse classes include reining, working cow horse, trail, cutting, and Western riding.

 Equitation (Hunter Seat, Saddle Seat, and Stock Seat): youth classes only
 Western Horsemanship (youth only)

TRAINING: IMPACT OF INDUSTRY

The Arabian and Half-Arabian are versatile breeds, as shown by the many sports in which they compete. These include halter, endurance (see Chapter 118), pleasure, jumping, dressage, reining, cutting, and racing (see Chapter 111). Young performance horses are not shown under saddle until they are 3 years old. They then compete in futurity classes for horses 3 years of age or junior horse classes for horses 5 years of age or younger. Because these horses do not compete in performance classes until 3 years of age, this allows more time for adequate skeletal development compared with racehorses and Quarter Horses that start training before 2 years of age. The reason that training of Arabian show horses is started later than some other breeds may be partly smaller size and late maturation, but it is also related to the fact that no performance classes are available for 2-year-olds, and therefore no economic incentives exist to start intensive training early.

Early training and conditioning typically involve a substantial amount of work in a round pen or by lunging. Excessive training in small circles causes increased torque on the joints and support structures of the distal aspect of the limbs. Young horses trained in this manner commonly develop bilateral distal forelimb lameness involving numerous structures. These problems tend to be exacerbated by uneven and excessively hard or deep footing.

Rules govern the shoeing of Arabian and Half-Arabian show horses. The rules vary with age, breed, discipline, and the country of the competition. Foot length, shoe weight and shape, and pad usage are individualized for each horse to optimize the height and arc of flight of the forelimbs and hindlimbs. In English Pleasure horses, a common shoe is the toe-weighted shoe, constructed by forging more steel in the toe of the shoe. The long foot and weighted shoes are used to enhance forelimb motion. Unfortunately this can contribute to strain on the suspensory ligament (SL) and joints of the distal aspect of the limb.

In all performance divisions horses are shown in a collected frame. In each division the type of work performed, the body position required, and the conformational defects of an individual horse contribute to the common lameness conditions. Differences are apparent in gaits, degrees of collection, and head and neck position in the various divisions. In the English Pleasure division, for example, the degree of collection, neck elevation, and poll flexion required shift weight to the hindlimbs and increase the work of the back and abdominal muscles. These positional factors can cause hindlimb lameness (especially involving the stifle and SL) and back pain. In the Western Pleasure and Reining divisions, similar problems are seen because of the amount of collection required. These horses also incur a variety of lameness conditions because they commonly are worked for longer periods than English Pleasure horses. In the Western Pleasure and Reining classes, because any departure from a quiet, steady position is penalized, fatigue can be part of the class preparation.

CONFORMATION AND LAMENESS

Mild-to-moderate carpus valgus and toed-out conformation commonly are seen and do not appear to have a major impact on soundness (Figure 123-1). One reason is that the carpus is not a common location for lameness. If these conformational faults are severe, horses are at risk of suspensory desmitis. Horses with long sloping pasterns, back-at-the-knee conformation, or offset knees are also predisposed to suspensory desmitis. These conformational faults are more common in the Half-Arabian and National Show Horse than in purebred Arabians and are more common in certain pedigrees.

Horses with low, underrun heels certainly are prone to lameness from palmar foot pain. This fault can be difficult to correct, even with careful attention to shoeing and trimming. A small, upright, contracted foot (club foot) can be a source of lameness and appears to be increasing in incidence. Inflammation of the soft tissues such as the SL, accessory ligament of the deep digital flexor tendon (ALDDFT), palmar foot structures, and distal sesamoidean ligaments tend to be more common in horses with club foot conformation.

A long, weak (sway) back and a short croup may predispose horses to soreness in the thoracolumbar, sacroiliac, and gluteal areas. Because problems in these areas are a common cause of poor performance, this type of conformation is a serious fault. Horses with cow-hocked conformation are the rule rather than the exception, but this conformation seems to have little effect on soundness.

Fig. 123-1 • A 4-year-old Half-Arabian with toed-out, carpus valgus, back-at-the-knee conformation. These are common conformation faults in the Arabian and Half-Arabian breeds and may predispose the horses to suspensory desmitis.

LAMENESS EXAMINATION

History

When describing lameness, trainers often comment that problems occur or are more noticeable during the first direction or the second direction of the show ring. This refers to the directional order in which rail classes are run. In the first direction horses enter the ring and travel counterclockwise (on the left rein), and in the second direction horses travel clockwise (on the right rein). Important questions regarding history include the division in which the horse competes; onset, degree, and progression of the lameness; previous or current treatment; and response to therapy. Additional information that can be helpful includes knowing which direction is harder for the horse at the trot (jog) and canter (lope), whether the horse pulls unevenly on the reins, whether the horse tracks straight in each direction, whether the horse falls out of leads behind (in the hindlimbs) in corners (i.e., becomes disunited in canter or breaks from canter to trot), and whether the rider rides the correct or incorrect diagonal in each direction (the horse may throw the rider up on one diagonal preferentially).

The age of the horse is important, because osteochondrosis is more likely to affect young horses recently started into training than older horses, but in older horses osteoarthritis (OA) is common. It is important to find out when the horse was last shod, and if any recent shoeing changes have been made. Altering medial-to-lateral hoof balance or hoof angle may increase pressure in certain areas and lead to bruising of the heel or sole. Increasing the hoof angle by raising the heel may increase load on the SL, which may lead to suspensory desmitis. The type and condition of the footing the horse has been working on is important to consider. Often footing at shows is less than ideal and in many cases is too hard, leading to the development of bruised feet. Conversely, if footing is too deep, it may lead to tendon and ligament injuries.

STATIC EXAMINATION

Visual Examination

Stepping back to visually examine the horse for overall symmetry of the limbs and upper body is helpful. Asymmetry of upper limb muscle groups may be a sign of atrophy from denervation, chronic lameness, or neurological disease. Asymmetry in the height and position of the points of the shoulders, the tubera sacrale, the tubera coxae, or the tubera ischii can indicate subluxations or fractures. The size, shape, and symmetry of the feet are important to note. Abnormalities such as club feet, an underrun or sheared heel, growth rings, dished dorsal hoof walls, and a contracted heel are some of the more common problems. Joint swelling, soft tissue swellings, poor conformation, scars, and abnormal structures such as splints are recognized quickly.

Palpation

Thorough palpation of the distal aspect of the limbs is performed with the horse in weight-bearing and non-weight-bearing positions. Degree of joint and tendon sheath filling; abnormal contours of bones, tendons, and ligaments; and intensity of the digital pulse amplitudes are best evaluated while the horse is bearing weight. With the limb elevated, painful response to palpation of tendons, ligaments (origins and insertions), and splints; pain on joint flexion; and range of motion of joints are assessed. Effusion of the distal interphalangeal (DIP) and stifle joints (especially the medial femorotibial joint) is common. To evaluate filling in the medial femorotibial joint, it is helpful to have the horse bearing weight with the limb being palpated slightly cranial to the opposite limb and perpendicular to the ground.

Response of an Arabian or Half-Arabian to palpation of the SL varies greatly, depending on the horse. Differences between limbs should be considered important, and change in the response over time is noteworthy. Many horses have a pain response to palpation of the SL but have primary lameness localized to the foot. Possibly the SL is painful because of a compensatory gait caused by a primary foot problem. In contrast, absence of inducible pain, especially in the proximal suspensory region, does not rule out this area as a source of pain causing lameness.

Careful palpation of the cervical, thoracic, and lumbosacral regions is useful in diagnosing the reason for poor

performance and lameness. Asymmetry, abnormal contours, and painful response to palpation are important to assess. Particular attention should be paid to the thoracolumbar musculature, the spinous processes, and the sacral tuberosities, because these areas commonly are involved in horses that perform poorly.

Hoof Tester Examination

Many Arabian and Half-Arabian show horses wear full pads in front during training and showing. Although sometimes inconvenient, especially at a competition, removing the shoe and pad for a complete hoof tester examination is helpful if the veterinarian suspects a foot problem. Some indication of painful areas may be obtained with the shoe and pad on, but many areas can be missed. Bruised heels and soles are common, especially at shows where footing may be too hard and horses are being worked longer than normal. Bruised heels and soles are two of the most common sources of lameness. Improvement in lameness can be dramatic if areas of bruising can be trimmed to reduce pressure or if the shoe is modified to eliminate weight bearing on a bruised area. Many horses show pain when hoof testers are applied across the heel but no pain with an individual heel bulb, the sole, or the bars of the hoof. These horses are in as much pain with the shoe and pad on, and therefore this situation may relate to structures deeper in the heel of the foot, rather than simply bruising of the sole.

Medial-to-lateral hoof imbalances may contribute to lameness and should be addressed whenever lameness exists and sore feet have been identified with hoof testers. In general, pain is associated with the high side of the foot or that area making ground contact first.

Pain in the toe region occurs less commonly than in the heel, especially for horses in the English and Park divisions, and likely is related to the way the foot is trimmed. These horses usually have a long toe and thick sole that may protect sensitive structures from bruising and exaggerate heel-first landing in the forelimbs. When pain over the middle of the frog is detected, bruising, palmar foot pain, or navicular-related pain should be considered. Diagnostic analgesia should be performed to confirm the relevance of hoof tester examination, because false-positive reactions occur.

DYNAMIC EXAMINATION

Flexion Tests

Flexion tests are important, but responses should be interpreted carefully. A painful response to flexion of joints and the degree of lameness should be assessed. Many false-positive distal limb flexion tests occur in Arabian and Half-Arabian show horses. Many horses without lameness show pain to static flexion and a positive response when trotted. In a lame horse a distal limb flexion test is not specific. For example, in a lame horse with a positive response to a distal limb flexion test, lameness may be localized anywhere from the foot to the distal metacarpal region. Carpal flexion usually is performed only in a static situation because we do not feel that substantial additional information is gained by trotting the horse. Horses that resent carpal flexion may have proximal suspensory desmitis (PSD), superficial digital flexor tendonitis, or carpal

tenosynovitis, because bony injury of the carpus itself is unusual in Arabian and Half-Arabian show horses.

Initially the entire hindlimb is held in flexion and then individual distal limb flexion and proximal limb flexion tests are performed. We attempt to stress the stifle independently of the tarsus by holding the distal tibia upward and behind the horse for 60 seconds. This test can also elicit pain from the lumbosacral and sacroiliac joint regions. These flexion tests are not specific, but they may increase the index of suspicion in a certain area. For example, horses with hindlimb PSD or distal hock joint pain respond positively to proximal limb flexion and must be differentiated based on the results of other tests. Mildly positive hindlimb flexion test results can be seen in sound horses that are actively training and showing. These mildly positive flexion test results may be related to subtle lameness or subclinical pain, or could be a normal response. For horses that have been competing successfully to have a moderate-to-severe positive response to a distal limb flexion test after a lengthy show is not unusual. This fact needs to be taken into account when prepurchase examinations are performed directly after horses have competed.

Examination in Hand and under Saddle

Horses should be examined at the walk and at the trot on the straight in hand. It is also helpful to examine horses at the walk in a figure-eight pattern. Examination on both hard and soft surfaces can be helpful. If possible, examining the horse at all appropriate gaits on the lunge line (or long line) and under saddle or in a cart is helpful. Multiple-limb lameness, especially contralateral forelimb and hindlimb lameness and bilateral front foot lameness, is common, which is important to keep in mind. The possibility of subtle neurological deficits should be considered during all phases of the lameness examination. In some horses lameness may not be apparent unless the horse is under tack and working near the higher end of its performance capabilities. This type of lameness is more difficult to diagnose, and diagnostic analgesia is usually required. Subtle lameness can be masked by a rider restricting free head movement or by controlling body position. The diagonal on which the rider sits can alter the appearance of lameness. When riding the *left* diagonal, the rider sits when the left forelimb and right hindlimb bear weight, and on the *right* diagonal the rider sits when the right forelimb and left hindlimb bear weight. The correct diagonal is the *left* when trotting clockwise and the *right* when trotting counterclockwise. In general a horse appears more lame behind when the rider sits when the lame limb is bearing weight, and the horse may try to throw the rider to the opposite diagonal. A horse with right hindlimb lameness appears more lame when the rider sits on the left diagonal. In Park, English, or Country English Pleasure classes, where riders are not penalized for riding the incorrect diagonal, horses often are ridden on the diagonal that minimizes lameness. Often a lameness is involved when a horse is seen being ridden on the incorrect diagonal when traveling in one direction and on the correct diagonal going the other way. These horses are referred to as *right* or *left diagonal* horses. An inconsistent relationship exists between the degree of forelimb lameness and the diagonal on which the rider sits, but lameness may be modified by switching diagonals.

It is important to note whether the observed lameness is constant regardless of direction or pattern. It is important to note if lameness varies, whether the involved limb is on the inside or outside of a circle, whether the horse is on the straight or in a turn, and whether lameness is worse when the horse is on hard or soft ground. The only gait deficit visible in horses with subtle forelimb lameness may be a slight difference in the height or arc of flight of the involved limb. Often a head nod is absent, but the horse appears unsteady in the face (movement of the nose from a fixed position) because of the discomfort of the limb from landing or from pushing off the ground.

DIAGNOSTIC ANALGESIA

If possible, it is important to perform diagnostic analgesia to confirm the source of pain. For example, many horses that appear to have foot pain because of sensitivity to hoof testers or pain on palpation of the SL actually have pain elsewhere. Under United States Equestrian Federation (USEF) rules, with a properly filed medication report, local anesthetic solution such as mepivacaine can be administered up to 24 hours before a class.

If lameness is to be reassessed with the horse under saddle or in a cart, intraarticular rather than perineural nerve blocks are preferred, because of possible loss of proprioception, which may lead to tripping or stumbling. After perineural blocks, horses may pull shoes or show an altered or awkward gait regardless of the lameness. If perineural blocks are performed in horses under saddle or in a cart, the rider or driver should be cautioned. Hindlimb nerve blocks can be difficult in uncooperative horses, and a tranquilizer (10 to 15 mg acepromazine intravenously) may be administered to fractious horses. Lameness may be more obvious after a tranquilizer is administered, but the risk of permanent penile prolapse with the use of acepromazine in stallions or geldings should be considered. In some horses, diagnostic analgesia of the hindlimbs may be impossible. On occasion the response to intraarticular medication, administered under heavy sedation, may be assessed as a diagnostic aid. Other diagnostic procedures such as nuclear scintigraphy, radiographic and ultrasonographic examinations, and magnetic resonance imaging (MRI) may be employed.

NEUROLOGICAL EXAMINATION

An Arabian or Half-Arabian show horse with neurological disease may show subtle to overt clinical signs of lameness, weakness, or ataxia, which may be mistaken easily for signs of musculoskeletal pain. Watching the horse turn in tight circles, back up, and walk a figure eight can be performed quickly and may pinpoint subtle deficits that were not noted or were less noticeable earlier in the examination.

Traumatic injuries caused by fractious horses falling during handling and training and equine protozoal myelitis are common causes of neurological disease and dysfunction in Arabian and Half-Arabian show horses in North America. OA of the caudal cervical facets is common, but is not necessarily of clinical significance. Clinical signs can include focal muscle atrophy, reduced lateral flexion of the neck, and subtle or overt forelimb lameness and ataxia. Radiographic examination and nuclear scintigraphy may

be helpful in diagnosis. Ultrasound-guided injections of the cervical facet joints are commonly performed. Two rare neurological conditions that may be confused with lameness and are much more common in Arabians than in any other breed are cerebellar abiotrophy and occipito-atlantoaxial malformation. Cerebellar abiotrophy is a congenital neurological abnormality that may have an inherited susceptibility and has been reported only in the Arabian horse and Gotland pony. Typical signs occur around 2 to 4 months of age and include head tremor, incoordination, hypermetria, and proprioceptive deficits. Horses may live into adulthood, and anecdotal evidence suggests that the condition may stabilize or improve, although for these horses to improve sufficiently to be useful performance horses is unlikely. Occipito-atlantoaxial malformation is an inherited congenital malformation that has been reported most frequently in Arabians. The severity of clinical signs varies greatly, from splinting of the neck to progressive ataxia and weakness to congenital tetraparesis. Reduced atlantooccipital movement and abnormal head carriage with the neck extended are common findings.² Diagnosis is confirmed radiologically (see Figure 53-4, B). Developmental cervical vertebral anomalies also may cause ataxia.

UNDIAGNOSED LAMENESS

When a diagnosis of the cause of lameness cannot be made after all available diagnostic procedures have been performed, a veterinarian should consider the following:

1. Tack problems: A poorly fitting saddle may create abnormal pressure on the withers or lumbar region and cause poor performance or lameness. A poorly fitted bit or bridle that causes the horse to flip its head or lean into or away from the bit also can affect performance greatly.
2. Dental problems (causing behavior that may lead to poor performance): Sharp enamel points, wolf teeth, and fractured or infected tooth roots may all cause abnormal head carriage and poor performance.
3. Painful skin lesions in the area of the girth, saddle, or bridle may affect performance.
4. A poorly skilled rider pulling on the horse while posting or with poor balance or timing may affect the horse's performance.
5. Recurrent exertional rhabdomyolysis affects performance.
6. Subtle neurological deficits may affect performance.

If these problems are ruled out and a diagnosis still cannot be made, the veterinarian could try empirical treatment including a period of rest, a course of nonsteroidal antiinflammatory drugs (NSAIDs), systemic corticosteroids, intravenously administered hyaluronan, oral or systemic polysulfated glycosaminoglycans (PSGAGs), acupuncture, or chiropractic manipulation.

TEN MOST COMMON LAMENESS CONDITIONS OF THE ARABIAN AND HALF-ARABIAN SHOW HORSE

1. Bruised and inflamed feet
2. Osteoarthritis of the distal interphalangeal joint and palmar foot pain

3. Suspensory desmitis
4. Osteoarthritis of the stifle joints
5. Thoracolumbar, sacroiliac, and gluteal pain
6. Osteoarthritis of the metacarpophalangeal and metatarsophalangeal joints
7. Distal hock joint pain
8. Splint bone injuries
9. Osteoarthritis of the proximal interphalangeal joint
10. Desmitis of the accessory ligament of the deep digital flexor tendon

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Bruised and Inflamed Feet

Differential diagnosis for lameness in the foot of an Arabian or Half-Arabian show horse includes sole bruising, osteitis of the distal phalanx, foot abscess, penetrating wounds, fractures, laminitis, navicular syndrome, OA of the DIP joint, collateral desmitis of the DIP joint, and palmar foot pain. The most common foot problems are bruising, OA of the DIP joint, and palmar foot pain.

Bruising is diagnosed by finding localized or generalized pain in the sole and by ruling out other lameness conditions. Digital pulse amplitudes are usually normal at rest unless bruising is severe and commonly increase abnormally with exercise. Discoloration of the sole by hemorrhage usually occurs later and may not be seen with acute sole bruising. The most common causes of bruising are hard footing or poor medial-to-lateral hoof balance. The high side (longer when viewed from the palmar aspect) is usually the bruised side, and treatment may be as simple as balancing the hoof. If hoof balance is judged to be adequate, then a pad can be cut out or the shoe can be beveled to reduce pressure on the bruised area. A common problem is a low, underslung heel. One foot may be affected, whereas the other tends to be upright or club footed. Horses with low, underslung hoof conformation commonly develop a bruised heel. Although raising the heel angle with a degree pad may appear desirable, this correction actually may cause further heel bruising by concentrating the force on the heel. We recommend the use of both a bar shoe and frog pads or a pad cut out over a heel bulb. The shoe may also be gently rockered into the pad (by grinding the heel portion of the pad) to reduce impact at the heel.

Horses with club foot conformation also may develop a contracted heel. Treatment involves identification and medical treatment of any existing palmar foot pain and shoeing fully in the quarters. Some horses with a low, underslung heel or with club foot conformation may not be lame, and therefore attempts at correction should be tempered.

In a flat-footed horse, sole bruising may occur in areas underlying the shoe, where the sole is not concave enough to prevent contact with the shoe or pad. In these horses a concave inner surface shoe should be used. Pads and packing material are important in treating and preventing bruised feet, but bruising can still be a problem. Silicone, tar, and oakum and newer products such as advanced cushion support are commonly used packing materials. However, if the packing is too firm, it may create rather than prevent sole bruising. Radiographs should be obtained to measure sole depth. A minimum of 15 to 20 mm of sole

at the toe region of the distal phalanx is required. Venograms are useful for identifying areas and severity of vascular compression to aid in shoeing and in deciding aftercare. Osteitis of the distal phalanx refers to a noninfectious inflammation of the distal phalanx, which in many horses appears to occur secondary to chronic sole bruising. The diagnosis is made radiologically by observing radiolucent changes and modeling along the solar margins and proliferative new bone along the dorsal aspect of the distal phalanx. Horses that have these radiological changes in the toe region also may have chronic bruising, laminitis, solar margin fractures, or club-footed conformation. In the heel the margins of the distal phalanx are normally irregular and less well defined radiologically, and a distinction between bruising and osteitis is harder, if not impossible, to make. In most horses, however, the treatment is similar.

Treatment of horses with acutely bruised feet also includes the administration of NSAIDs and physical therapy. If treatment is necessary during or close to a show in North America, NSAIDs must be given according to the USEF rules for therapeutic medication under which the Arabian and Half-Arabian divisions operate. The 2008 guidelines state that horses can receive phenylbutazone at a dose of 4.4 mg/kg once daily for 5 days in a row no closer than 12 hours before a class. If 2.2 mg of phenylbutazone per kilogram is given by mouth every 12 hours, then the drug can be administered at any time before a class. Under USEF rules, two NSAIDs from a list of seven (flunixin meglumine, ketoprofen, naproxen, meclofenamic acid, firocoxib, diclofenac, and phenylbutazone) are allowed to be given at the same time, except that phenylbutazone and flunixin meglumine may not be given to the same horse within 7 days of a class. If bruising is severe and a second NSAID is required, intravenously administered ketoprofen (2.2 mg/kg sid) is helpful. This should be given no closer than 6 hours before a class. Specifics of NSAID use at USEF competitions are listed in the USEF handbook and can be viewed online. Isoxsuprine (400 mg orally [PO] bid) can be used to increase blood flow to the foot and, although controversial, appears to be helpful in many horses.

Physical therapy includes standing the horse in ice (15 minutes in and 15 minutes out for three repetitions, repeated several times a day) for the first 24 hours, followed by soaks in hot water and Epsom salts (15 to 20 minutes, three times daily). After soaking, the bottom of the foot can be packed with a poultice and wrapped. An effective poultice is a slurry of dimethyl sulfoxide (DMSO) and Epsom salts. If areas of the sole are particularly soft, painting on a mixture of formaldehyde hardens the sole. Feet with weak or damaged walls should not be soaked.

Osteoarthritis of the Distal Interphalangeal Joint and Palmar Foot Pain

Synovitis or acute inflammation of the DIP joint is common and likely represents an early form of OA. Lameness is usually mild to moderate and frequently is bilateral. Lameness tends to be more obvious in circles or tight turns, frequently with the affected limb on the *outside* of a circle. When horses are affected bilaterally, the only signs may be a shortened cranial phase of the stride and reluctance to go forward. Effusion of the DIP joint can be palpated just proximal to the coronary band on the dorsal aspect of the limb. Horses may show pain when hoof testers are

applied across the heel, but examination of the sole of the foot is unremarkable, unless other problems such as bruising or navicular syndrome are present. Many young horses develop DIP synovitis early in training and lameness improves with a short period (14 to 28 days) of rest and the administration of NSAIDs. DIP synovitis is also common in older show horses, in which it may be associated with poor foot conformation or a heavy show schedule.

No radiological abnormalities are detected unless the condition is chronic and advanced OA develops. Lameness is abolished by analgesia of the DIP joint or palmar nerve blocks at the base of the proximal sesamoid bones (PSBs). Mepivacaine (3 mL) deposited over the medial and lateral palmar digital nerves just above the bulbs of the heel also substantially alleviates pain originating from the DIP joint.³ Analgesia of the DIP joint is not specific, but use of a small volume (6 mL) of local anesthetic solution and evaluation of the response within 6 to 8 minutes may minimize the effects of diffusion into the digital nerves and inadvertent misdiagnosis.

It is important to remember that several problems may coexist in the foot, and sorting out a single specific diagnosis can be difficult. Horses with a low, underrun heel often have bruising, osteitis of the distal phalanx, and OA of the DIP joint. Horses with navicular syndrome may have bruising in the toe area related to decreased weight bearing on the heel. Scintigraphic examination may be useful in differentiating these potential causes of lameness.

Horses with early, acute OA of the DIP joint should be evaluated clinically for abnormalities of hoof balance and hoof angle. Shortening and rolling the toe of the shoe or rockering the shoe into the pad to ease breakover can be helpful. Shortening the toe in English show horses may not be well accepted by trainers because they think it decreases the desired forelimb action. If the lameness is moderate or severe, the horse should be allowed to rest for 30 days or the workload should be reduced drastically. Intraarticular medication with hyaluronan (20 mg) and a corticosteroid (40 mg methylprednisolone acetate or 6 to 10 mg triamcinolone acetonide) and systemic phenylbutazone (2.2 mg/kg PO bid for 5 days) are recommended. Intraarticular medication with interleukin-1 receptor antagonist protein (IRAP), usually as a three-dose series, is a useful alternative treatment. If lameness is mild, training can resume 2 to 3 days after the injections. Treatment with hyaluronan (40 mg intravenously once a week for 3 weeks) or PSGAGs (500 mg intramuscularly once every 5 days for four to seven treatments) sometimes is used also, but it should not be a substitute for intraarticular therapy. These products frequently are used as "maintenance" medications (one dose every 2 to 4 weeks) and for preshow medication (one dose 24 to 72 hours before a class) for joint-related lameness.

Palmar foot pain is a frequent cause of lameness. Horses may or may not show pain on hoof tester examination, but lameness is eliminated by palmar digital analgesia. Causes include navicular syndrome, deep digital flexor tendonitis, distal sesamoidean impar desmitis, collateral sesamoidean ligament injury, inflammation of the navicular bone, fragmentation of the distal border of the navicular bone, and congenital bipartite or tripartite navicular bones. Reaching a specific diagnosis in some horses may be difficult. Radiology, ultrasonography, and MRI may be used to determine the specific cause(s) of lameness.

Although it is important to identify the source of lameness as specifically as possible, the treatment options in horses with palmar foot pain are somewhat limited and similar regardless of the cause. Rest, systemic corticosteroid and NSAID administration, therapeutic shoeing, extracorporeal shock wave therapy (ESWT), medication of the DIP joint or navicular bursa and the administration of tiludronate in horses with navicular involvement, and palmar digital neurectomy are the most common treatments. Mesenchymal stem cell or platelet-rich plasma (PRP) injections may be used to treat horses with distal deep digital flexor tendon (DDFT) lesions. Natural balance shoes are not used routinely for English and Park horses because they decrease forelimb motion.

Suspensory Desmitis

PSD is one of the most common lameness conditions of the metacarpal and metatarsal regions. Although more prevalent in the forelimb, PSD is a common hindlimb problem and typically is an insidious lameness but may have an acute onset. Lameness is more obvious when the affected limb is on the outside of a circle and is worse on turns than in straight lines. Usually no swelling is detectable, and the response to palpation is unreliable. Definitive diagnosis is based on the response to diagnostic analgesia, combined with radiological and ultrasonographic examinations. Many treatments are available, including the use of systemic antiinflammatory agents; local injections of antiinflammatory agents or counterirritants; intraleisional injections of mesenchymal stem cells or PRP; topical agents with support wraps; ESWT, magnetic, laser, and ultrasound therapies; and various surgical procedures.

A decision must be made whether the horse is sound enough to remain in work, as in horses with a chronic low-grade PSD, or whether the horse should be allowed to rest. If the horse is to remain in work and local injections are to be part of the treatment regimen, a veterinarian has two options. An antiinflammatory agent such as a short-acting corticosteroid, possibly mixed with hyaluronan or a PSGAG, may be used, followed by a few days of handwalking, before the horse resumes work. Alternatively, a counterirritant such as 1 to 2 mL of 2% iodine in almond oil is injected, followed by continued work. In both instances the work is limited to graduated periods of walking and low-speed trotting for several weeks. The walking and trotting generally are performed in escalating timed intervals. The canter or lope is not recommended initially, because the affected limb is the only limb on the ground for a portion of the gait sequence. The weight of the shoes and pads may be reduced during the initial portion of the recovery period. If the injury is too severe for the horse to remain in work, the horse is confined and handwalked until recovery is sufficient to begin a regimen of low-impact, controlled exercise. These horses are not turned out, because they tend to reinjure themselves with free exercise.

PSD tends to recur with prolonged intense exercise. Horses with bilateral club feet, low underrun heels, one club foot and one foot with a low heel, or substantial rotational and angular deformities are predisposed to PSD. Horses with a chronic lameness in the contralateral limb or the diagonal limb also are predisposed to lameness because of compensatory loading. It is important to identify other

problems, because resolution of lameness in another limb may be crucial to the long-term resolution of PSD.

Suspensory branch desmitis also occurs frequently. An acute injury causes pain, heat, and swelling over the affected branch and a positive response to distal limb flexion. Usually some distention of the fetlock joint capsule occurs. Diagnosis is confirmed by ultrasonography, and the PSBs should be evaluated radiologically. Horses with acute injuries are treated symptomatically with ice, poulticing, NSAIDs, and systemic corticosteroids. If sesamoiditis is present, isoxsuprine or pentoxifylline treatment may be helpful. The shoeing should be evaluated, and imbalance (frequently a low heel bulb on the affected side) corrected. If possible, the toe should be shortened, or a rolled toe shoe should be used to ease breakover. Horses with chronic active suspensory branch desmitis may benefit from injection of corticosteroids (methylprednisolone acetate and isoflupredone acetate) subcutaneously in the affected area. Most horses are managed similarly to horses with PSD. Suspensory branch desmitis tends to recur, can be difficult to manage successfully, and may be a career-ending injury.

Suspensory desmitis in the hindlimbs also occurs frequently. Horses with camped-out conformation may be predisposed. Diagnosis and treatment are similar to those described for forelimb desmitis. In hindlimb PSD compartment syndrome may be identified. Transection of the proximal metatarsal retinaculum (fasciotomy) can be helpful. Hindlimb PSD is often chronic, and horses require periodic therapy to remain sound.

Osteoarthritis of the Stifle Joints

The stifle is a common source of lameness, and apart from occasional acute injuries most often horses have chronic, low-grade lameness that may not be evident when examined in hand. Riders may complain that horses are hard on one side of the mouth, tracking with a shoulder or hip in or out, falling out of a hind lead in the corners (becoming disunited in canter or breaking to trot), and bending poorly. Horses with stifle pain also have difficulties in downward transitions, because they cannot maintain a collected frame and tend to fall out behind. If a horse is forced to maintain collection, the head may be raised. Horses exhibit increased discomfort going downhill. If the work area has even a slight grade, an affected horse appears more comfortable going up the grade than down. Horses also fatigue easily in deep footing, with loss of collection, diving forward in the bridle (English divisions), raising out of the bridle (Western and Hunter divisions), and loss of hindlimb cadence at the trot. Lameness is worse in turns and improves in the straight portions of the arena.

The medial femorotibial and femoropatellar joint capsules may be distended, and fibrous thickening from a previous medial patellar desmotomy or desmoplasty (splitting) and other abnormalities from previous injuries may be apparent. Various flexion tests, such as pulling the limb caudally, may exacerbate lameness, but these tests are not reliable and may be dangerous to perform. Intraarticular analgesia usually is required. The medial femorotibial joint, the femoropatellar joint, and the lateral femorotibial joint are affected with decreasing frequency and generally are blocked individually in that order. Radiographic examination should include caudocranial, lateromedial, and oblique

images. Ultrasonographic examination, nuclear scintigraphy, and diagnostic arthroscopy are sometimes required.

Most commonly lameness is improved by intraarticular analgesia of the medial femorotibial joint, but radiological findings are negative or equivocal. Affected horses are thought to have chronic inflammation of the soft tissues of the joint and synovitis. Some of these horses eventually develop an enthesophyte on the proximal medial aspect of the tibia. Lameness often recurs, because lameness reflects the type of work the horse performs, the collected frame required, and conformational weaknesses, such as lack of angulation in the hip, stifle, and hock, camped-out conformation, and weak hindquarters in general. The condition is managed by adapting the work level between shows and the show schedule of the horse to accommodate for lameness, by corrective shoeing, and by using systemic antiinflammatory agents and intraarticular medication. Corrective shoeing is individualized but involves trimming the foot short and using a light shoe that assists breakover. Increasing the hoof angle in a long-toed low-heeled foot can be helpful. Many horses break over the dorsomedial aspect of the toe, and that portion of the shoe can be rolled or shaped to ease breakover. A worn shoe can be examined for breakover location (*Figure 123-2*). Some horses are more sound barefooted behind and compete that way. To maintain soundness at shows, horses are maintained at a work level between shows that does not require intraarticular treatment. Systemic administration of hyaluronan and a PSGAG may help. Systemic and intraarticular antiinflammatory therapy is begun before competition to minimize lameness during the competition. If a horse requires frequent therapy between shows, it has a poor chance of enduring a competition in good form.

Counterirritant therapy in the form of 2% iodine in oil commonly is injected in various patterns along the patellar and collateral ligaments of young horses, in horses with loose stifles, and in horses that have been rested as the

intensity of training increases and that exhibit nonspecific pain or weakness in the stifle area. Counterirritants are not used as a replacement for intraarticular therapy but may be used concurrently. Injections usually are limited to 1 to 5 mL to reduce postinjection inflammation and to decrease scarring from numerous injections. Work is continued, but the intensity is reduced for a short time as the horse recovers.

Osteochondrosis is the second most common problem seen in the stifle. Osteochondral fragments from the femoral trochleas can be removed arthroscopically; usually horses have a favorable prognosis. Horses with lameness caused by subchondral bone cysts in the medial femoral condyle have a poorer prognosis. Some horses respond to intraarticular or intralesional corticosteroids. Surgical treatment may fail to resolve the lameness.

Thoracolumbar (Back), Sacroiliac, and Gluteal (Croup) Pain

Work-related back and croup pain is common in horses because of working in a collected frame frequently or for extended periods, compensatory altered carriage caused by injuries to the distal aspect of the limb, poor saddle fit, poor balance and timing of a rider, injuries from falling and weakness from immaturity, lack of conditioning, or poor conformation (long, weak back).

Back pain should be suspected when behavioral changes such as kicking out during lead changes in canter and uncharacteristic bucking occur. The horse is observed for muscle asymmetry while it stands with the body straight and the limbs squared on a level surface. The back and croup are palpated for areas of pain, using gradual pressure with the flat surface of the digits. Flexion, extension, and lateral flexion of each area of the back should be induced, and ease of mobility evaluated. Unilateral abnormalities may indicate concurrent injuries to the distal aspect of the limb. Unilateral lumbar pain often results from compensatory carriage of the hindlimbs to that side. Unilateral sacroiliac inflammation or dorsal ligamentous thickening often results from overbearing on that side from a chronic contralateral or diagonal limb injury. For example, horses with a chronic left front or left hind lameness may have swelling and pain in the area of the right tuber sacrale. Rectal examination is used to evaluate pelvic symmetry and ventral lumbar muscular pain. Other diagnostic modalities include radiography, ultrasonography, nuclear scintigraphy, and thermography, but physical examination remains the most important and reliable method of diagnosis. Myositis also occurs commonly and is diagnosed by history, observation of altered gait, palpation, and serum enzyme assay.

A variety of treatments is used, and these are discussed thoroughly elsewhere. Usually a period of rest is indicated, along with resolution of any associated lameness, followed by a period of reduced exercise. Systemic and local antiinflammatory agents are administered. Other therapies include cold and heat therapy, acupuncture, chiropractic therapy, massage therapy, and magnetic, electromagnetic, laser, and ultrasound therapy.

Successful treatment of horses with back and croup injuries depends on identifying initiating causes and making appropriate changes to alleviate these causes if possible. Educating the rider is also helpful, because changes

Fig. 123-2 • A left hind shoe indicating natural breakover medial to the toe area (medial is right). Future shoes will be formed to allow breakover in this area rather than directly at the center of the toe.

in training routines or tack may be helpful in preventing recurrence.

Osteoarthritis of the Metacarpophalangeal and Metatarsophalangeal Joints

Synovitis of the metacarpophalangeal and metatarsophalangeal joints, an early form of OA, causes effusion, pain on static fetlock flexion, and a positive response to a distal limb flexion test. The condition is frequently bilateral. Because mild effusion in sound Arabian and Half-Arabian show horses is seen commonly, it is important to perform intraarticular or perineural analgesia to confirm the source of pain when OA of the metacarpophalangeal or metatarsophalangeal joint is suspected. Radiological assessment is performed to determine the extent of osteoarthritic abnormalities. Many Arabian and Half-Arabian show horses perform well in spite of mild OA of the fetlock (Figure 123-3). Treatment is similar to that recommended for OA of the DIP joint, except that a shorter-acting corticosteroid such as triamcinolone acetonide or betamethasone is used for intraarticular medication.

Distal Hock Joint Pain

OA of the centrodistal and tarsometatarsal joints, called distal tarsitis, is common. Tarsal lameness is often bilateral, although one limb usually is affected more severely. Affected horses have reduced hock flexion at the trot and tend to travel with a hip off to one side, especially in the corners (drift away from the lame limb). Rider complaints

Fig. 123-3 • Lateromedial radiographic image of a metacarpophalangeal joint of a sound Half-Arabian show horse. There is a moderately sized osteophyte (arrow) on the proximal dorsal aspect of the proximal phalanx, reflecting osteoarthritis.

are similar to those regarding horses with stifle lameness. Western horses may tend to rate poorly and lope (canter) with a four-beat rather than a three-beat action. Reining horses tend to raise up in spins to the affected direction, bend poorly, stop unevenly or on the forehand, and change leads late behind in flying changes. Diagnosis is based on palpation, including the Churchill test, flexion tests, diagnostic analgesia, radiography, and occasionally ultrasonography and nuclear scintigraphy. Treatment consists of systemic administration of antiinflammatory agents and intraarticular medication with corticosteroids, possibly with hyaluronan (60 to 80 mg of methylprednisolone acetate and 10 mg of hyaluronan per joint), repeated as necessary, often two or three times during a show season. If medical therapy fails, chemical, laser, and surgical fusion techniques are available. ESWT and intravenous tiludronate administration have both been used successfully. Cunean tenectomy usually is not performed because the procedure commonly does not resolve lameness. Corrective shoeing involves inspecting the old shoe and squaring the new shoe to accommodate the breakover, setting the shoe back, shortening the toe, reducing the weight of the hind shoe, and occasionally using asymmetrical trailers.

Splint Bone Injuries

Proliferative periostitis, referred to as *splints*, and fractures of the second and fourth metacarpal bones and to a lesser extent fractures of the second and fourth metatarsal bones are common, especially in young horses. Diagnosis of splint-induced lameness is made using palpation, diagnostic analgesia, and radiography. Associated suspensory desmitis should be considered and assessed by ultrasonographic examination. Predisposing causes include conformational defects such as offset knees or base narrow and toed out. Heavy shoes and pads can exacerbate a tendency to wing in and cause interference. Poor footing that is excessively deep or hard can contribute to the development of splints. Immature horses in excessive work, or wearing shoes and pads that are too heavy for their level of fitness, are predisposed to splints. Shoeing with improper medial-to-lateral balance, obesity, and dietary imbalances can be contributory causes.

Proliferative periostitis originates from injury to the interosseous ligament, resulting in the development of proliferative fibrous connective tissue that subsequently mineralizes. Radiology is used to assess the injury and to determine the presence of fractures. Osteolysis of the third metacarpal or metatarsal bone and of the splint bone at the site of the injury is a sign of substantial inflammation and can indicate a prolonged recovery. Treatment includes rest (2 to 4 weeks), cold therapy, systemic and local administration of antiinflammatory agents, topical agents with support wraps, ESWT, and magnetic therapy. Large exostoses that interfere with surrounding soft tissue structures can be excised surgically.

Work-related fractures are predominantly distal, closed fractures and are thought to result from overexcursion of the SL during fetlock hyperextension. These fractures frequently are displaced, heal by nonunion, and tend to irritate surrounding soft tissues. For these reasons they commonly are removed surgically. Lameness in horses with mid-splint bone nondisplaced fractures often resolves

with conservative therapy. Initial therapy is similar to the treatment of a true splint, except that local administration of corticosteroids is not performed. If conservative therapy fails, surgical excision of the exostosis and distal portion of the splint bone may be performed. Horses with fractures of the proximal aspect of a splint bone are evaluated on an individual basis, because some respond to conservative therapy, whereas others require surgical intervention.

Osteoarthritis of the Proximal

Interphalangeal Joint

Incidental radiological changes (lippling and spurring) indicating mild OA of the proximal interphalangeal (PIP) joint in Arabian and Half-Arabian show horses are not uncommon. Moderate-to-severe OA, however, would be expected to cause chronic lameness. In most horses OA of the PIP joint is caused by chronic repetitive trauma, although OA secondary to a single severe injury is possible. In young horses osteochondrosis in the form of osseous cystlike lesions and fragmentation may be involved. The importance of any radiological abnormalities should be validated using diagnostic analgesia. Distal limb flexion is usually positive, and lameness should improve with palmar nerve

blocks at the base of or at the level of the PSBs or intra-articular analgesia of the PIP joint. Treatment is similar to that recommended for horses with OA of the DIP joint.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT occurs less frequently than does PSD and is usually diagnosed in horses with club feet or low, underrun heels. Footing that accumulates under the shoe, creating a rocking motion of the foot during the weight-bearing phase of the stride, may predispose horses to desmitis. Lameness is usually acute in onset, and palpation often reveals a painful thickening along the length of the ligament that can be confused with the DDFT. If the condition is chronic and low grade, diagnostic analgesia may be required. Diagnosis is confirmed with ultrasonography. Treatment involves prolonged rest and systemic and local administration of antiinflammatory agents, PRP, or mesenchymal stem cells. Adjuncts include cold therapy, topical agents with support wraps, and magnetic, laser, ESWT, and ultrasound therapy. Because the predisposing conformational defect remains, the condition tends to recur.

Chapter 124

Lameness in the Driving Horse

Kevin P. Keane and Graham Munroe

DESCRIPTION OF THE SPORT

This chapter deals with horses used for competitive driving purposes, those driven privately for pleasure, and those used as beasts of burden as a mode of transportation. The sport of driving horses in competition is relatively new and has many variations, requiring different types of horses performing different tasks. Certain breeds or breed types are perfectly suitable for one form of driving sport but not another, and variation in the size, type, and breed of horse used is considerable. Horses and ponies are used, and the term *horse* is used in this chapter to refer to both, except when specific reference to a pony is required.

In the United Kingdom and Europe there is a much greater availability of a variety of driving competitions than currently exists in North America. The sport is growing in Australia, South Africa, and South America. Pleasure driving includes presentation classes in the show ring and general driving on roads and tracks. Presentation classes are grouped broadly into hackney and nonhackney types, the difference being based on the phenotype of the horse as opposed to a breed registry. A competitor pays close attention to the harness, the attire of the driver, and an appropriate carriage to suit the horse, because judging is

subjective and relies on strict adherence to tradition, based on a suitable match of horses and carriage. The horses perform movements requested by the judges, and style and quality of the gaits are scored subjectively. These horses compete at the walk and trot (a park pace being roughly equal to a slow working trot). Pleasure driving events also can include drives at the walk or trot on roads and tracks of up to 5 to 10 miles.

Competitive driving includes combined driving or horse driving trials and scurry driving. Scurry driving is seldom seen in North America but has a strong following in the United Kingdom and other parts of Europe. Scurry driving consists of a single horse (mainly ponies) or more commonly pairs of horses competing over a tight, coned course in a show ring against the clock. The horses and carriages are often small to allow the narrow gates (the gap between a pair of cones) and corners to be negotiated at speed. Horse driving trials are a driven form of horse trials, or eventing, and like its ridden counterpart, driving is a highly athletic, physically demanding sport for the horse and driver.

Driving trials as an international equestrian sport started in 1968, when the Fédération Équestre Internationale (FEI) international rules were drawn up under the instigation of HRH Prince Philip, who was then the President of the Federation. The first international horse driving trials event took place in 1971 in Hungary. Initially the competition was only for horse teams (four-in-hand). A team is composed of four horses, two before two; those in front are called *leaders*, and those closer to the coach, *wheelers*. As the sport developed and individuals of more modest means entered the fray, competitions for singles (one horse), tandems (two horses harnessed one behind the other), and pairs (two horses harnessed side by side) rapidly blossomed. These classes were further divided into those

for ponies (less than 148 cm or 14.2 hands high) and horses. The sport is now structured at various levels depending on the ability of the driver and horse(s). Disabled driving has recently been introduced. The FEI is responsible for the international rules that cover the World and European championships and selected international events such as the Royal Windsor International Driving Grand Prix. The national associations liaise with the FEI and are responsible for running the national events and championships and producing national rules. Local driving clubs (found in Europe, the United Kingdom, and the United States) also run local events that may differ substantially in standards and requirements of competitors, but they essentially mimic FEI rules. Important events include the Royal Windsor (United Kingdom), Aachen and Riesenbeck (Germany), Breda (Holland), Saumur (France), Waregem (Belgium), St Gallen (Switzerland), and Fair Hill (United States). World championships are held every 2 years for singles, pairs, and teams for horses, and a European championship is held for pony teams. The World Equestrian Games, held every 4 years, which also host World Championships, allow four-in-hands only to compete. The first World Pony Championships (singles, pairs, and teams) were held in Saumur in 2003. Competitions in Europe run from April to September, with championships held toward the end of this period. However, in the last 5 years there has been a growth in indoor driving events, culminating in the FEI World Cup, which is a series of events within Europe. Indoor driving competitions often consist of three phases: precision and paces, cone driving, and time driving through marathon obstacles.

Horse driving trials consist of three phases—dressage, marathon, and cones—usually spread over 3 days, but in lower standard competition all three may take place over 1 to 2 days. The first phase is a driven dressage test, which consists of a set sequence of movements that are judged by a number of officials against a standard of absolute perfection. The test is designed to highlight the obedience, paces, and suppleness of the horse(s), and the skill of the driver in handling of the reins. The second stage is the marathon, which tests the fitness and stamina of the horse(s) and the judgment of pace and horsemanship of the driver. The cross-country marathon can be divided into three or five sections (depending on the level of competition); for each section a maximum and minimum time are allowed (Table 124-1).

The speeds and time allowances are adjusted for different classes, especially ponies. At the end of sections B and D are mandatory 10-minute halts. During the second of

these, the horses are subjected to veterinary checks for lameness, injuries, and fitness (respiratory rate, pulse rate, dehydration, temperature, and speed of recovery). Section E has eight obstacles. Each obstacle is made up of a number (up to six) of lettered gates. The aim is to drive through these gates (between white and red markers) within each obstacle in the correct alphabetical sequence in the shortest possible time. Most injuries occur on the marathon, although lameness may not become apparent until later, just before the third phase, the cone competition. The object of the cone phase is to test the fitness and suppleness of the horse after the marathon phase by driving through a course of narrowly spaced pairs of cones (up to a maximum of 20) within an allotted time. Each cone has a ball balanced on top of it that is dislodged easily if the horse or carriage strikes the cone. The winner of the competition is the competitor with the fewest penalty points.

Veterinary inspections of horses taking part in an event also occur before the dressage day, at the end of the marathon, and at the beginning of the cone competition. Lameness at any of these inspections usually leads to elimination from the event, although considerable variation exists in the definition of working soundness among veterinarians, particularly regarding hindlimb problems.

Horses used by Amish and Mennonite sects (United States) as beasts of burden are nearly always Standardbreds or American Saddlebred horses and are driven as singles. The horses are driven when needed, with no structured fitness training, and lameness is common.

TYPES OF HORSES USED

The type of horses used for driving varies considerably with the particular form of the sport or use to be undertaken. For pleasure and presentation driving, the type of horse used is related mainly to the size and type of the carriage and the overall effect the driver is trying to convey to the judges (e.g., country or town turnout, meaning an informal or formal appearance of the coach, harness, and driver's attire). Horses used include Shires, Clydesdales, and Percherons in heavy horse turnouts such as drays; Hackneys (including crosses), Thoroughbreds, and Warmbloods in smart town turnouts; Cobs, larger pony types such as Welsh Cobs, Welsh Section C, Dales, Fells, Fiordlanders, and Friesians in country turnouts; and smaller pony types such as Welsh Mountain Section A, Shetlands, New Forest, and Dartmoor in small carriage turnouts. The aforementioned breeds primarily cover the variety seen in the United Kingdom and Europe. In the United States Warmblood, Warmblood crosses, Welsh, Hackney, Morgan, and Friesians are used most often for pleasure and driving trials. Most presentation and pleasure driving is undertaken with a single horse turnout. The horses range from 4 to 20 years of age, and many have been or are used for other equestrian disciplines. Scurry driving usually involves single or pairs of small ponies or pony-type horses such as Shetlands, Welsh Mountain, New Forest, and Dartmoor. These ponies are often younger than pleasure-driving horses and are less likely to be used for other equestrian sports, except perhaps combined driving trials.

Horses used for driving trials must be older than 4 years of age before they can compete, and records show 19-year-old horses competing at world championship level. Many

TABLE 124-1

Basic Format of the Five-Stage Marathon			
	LENGTH	GAIT	AVERAGE SPEED (KPH)
Section A	≈10 km	Any type, usually trot	15
Section B	1 km	Walk	7
Section C	4 km	Fast trot	19
Section D	1 km	Walk	7
Section E	10 km	Trot, canter	14

of the best driving trial horses are 12 to 19 years of age and have been used earlier for other purposes. This long working life and slow introduction to work at a young age, together with little high-speed and more slow-speed conditioning work and regular winter breaks, has a considerable effect on the type of lameness seen in these horses. The types of horses and ponies used vary greatly. In continental Europe, Warmblood breeds are particularly popular; for example, Gelderlanders, Swedish Warmbloods, Dutch Warmbloods, Hanoverians, and Holsteiners, with a modern trait being ever-increasing size. In the United Kingdom less uniformity occurs in the horses used; for example, Hackney crosses, Cobs, Welsh Cobs, Lipizzaners, Lusitanians, Orlovs, and some Warmbloods and Thoroughbred crosses. The most popular ponies used for driving trials in Europe are Welsh Sections A, B, and C, Haflingers, and New Forest crosses.

In the practice radius of one of the authors (KK) is a unique opportunity to observe, evaluate, and diagnose lameness conditions in driving horses used by members of the Amish and Mennonite religious sects as a mode of transportation. Several regions throughout North America have populations large enough to provide a reasonable number of horse owners for which to provide veterinary services. The incidence of lameness is influenced by the necessity of driving reasonably long distances on asphalt surfaces (up to 30 miles [48 km] in one day), with sometimes a single horse pulling a Meadowbrook cart containing up to seven family members. Electricity is not used by the Amish sect and is consequently not available, so a veterinarian must be guided by the ability to palpate precisely and interpret the findings often without the adjunct diagnostic procedures relied on daily, such as radiography and ultrasonography. The veterinarian also faces great pressure because a lame horse may strand an Amish owner.

TRAINING

The training regimen for driving horses varies considerably depending on the type of driving to be undertaken and the level of competition to be attempted. Top-class horse driving trial horses require a regimented fitness program of up to several hours daily, with techniques for such fitness varying from trainer to trainer. In addition some time is spent practicing cone driving, and hazard training through schooling obstacles set up to mimic what is seen in competition. In pleasure or presentation driving, horses normally are worked intermittently, mainly on roads and tracks at the walk and trot, usually in the summer months, with a rest or turnout to grass in the winter. With the introduction of indoor winter competition, winter breaks may be reducing. In scurry driving the training required is more intense, with a combination of regular road work at the walk and trot to increase overall fitness, alongside school and field work concentrating on bending, suppleness, and turning at speed with accuracy. The scurry driving season can extend over longer periods of the year, when competition comes indoors. Amish horses attain a less quantitative level of fitness through irregular use and essentially no training.

Conditioning exercise tends to start in February, aiming for the first events in late April. Competitions are then available almost every weekend (Thursday to Sunday)

throughout the summer, culminating in the national and international championships in August to October.

The type or breed of horse used in driving and the way the horse is trained have an important effect on the type and incidence of lameness. Differences in conformation, gait, and size have an influence. Generally, ponies are less likely to develop lameness, are easier to train to fitness, and are more agile. When compared with horses, pony conformation and foot shape are better and they carry less weight. Unfortunately, alongside this general toughness is all too frequently allied a "cussed" temperament. Cob-types are similar to ponies in temperament and hardiness but are heavier and more powerful, often leading to low-grade osteoarthritis (OA) in later life. They often require considerable training to allow the necessary control and obedience to be obtained. Welsh Cobs and hackney-types and crosses have particularly exaggerated natural forelimb actions, which over long periods of use may increase wear-and-tear injuries in the forelimbs such as metacarpophalangeal joint problems. Some of the larger breeds, such as the Warmbloods, have poor conformation, especially in the hindlimbs, such as straight in the stifle and hock, which has a major effect on the incidence of lameness. Most driving horses are not broken to harness until they are 3 to 4 years old and are not worked until they are 5 to 6 years old. Therefore conditions prominent at an earlier age, such as osteochondrosis of the tarsus and stifle, are uncommon.

The incidence of lameness in driving horses is much influenced by a long working life; the training, which is mainly flat work at the walk and trot; the different stresses and strains placed on them by the carriage (increased pressure on the hindlimbs, especially distally); the regular rest periods during the driving career; slow start in life; and whether they have been used for other purposes, previously or concurrently. All of these factors contribute to a low incidence of lameness, especially from fractures or acute soft tissue injuries seen in racehorses, but an increased incidence of low-grade wear-and-tear injuries, particularly of the hindlimb joints. In recent years the increasing competition and prestige at the top end of the sport, particularly internationally, have led to increased demands on horses, less patience to wait for horses to mature or to become seasoned, and consequently more lameness.

GROUND CONDITIONS

Training is usually carried out on roads or tracks of varying surfaces, depending on the region and country involved. In the United Kingdom this is mainly tarmac roads and firm tracks, whereas in the eastern United States, tarmac, dirt, and gravel roads and pre-cut paths through agricultural fields predominate. Training for dressage and cones is usually in grass paddocks, although some drivers have access to all-weather areas. The variable, often hilly terrain in the United Kingdom and United States helps develop fitness. In Europe some of the competitions and areas for training are flat and have a sandy soil, which gives an even, absorbent, good surface for exercise. The firm surfaces on which many driving horses train and work tend to increase concussion to the feet and joints; recent evidence has shown bone density is increased (strengthened) by driving on such surfaces, but firm surfaces are unlikely to prevent injury to tendons and ligaments as was once

thought. Repeated concussion over many years may contribute to low-grade joint disease and means that good foot conformation and shoeing are imperative to help offset some of this constant trauma. The variable and unpredictable ground conditions present on marathon courses contribute to injuries to joints, such as the fetlock, and to ligaments and the digital flexor tendon sheath (DFTS).

CONFORMATION

The huge variety of breeds and types of horses used in driving means that no particular traits of conformation have been established as representative of this type of work. Many of the Warmbloods, which are the most common breeds on the continent of Europe and are now becoming so popular elsewhere in the world for riding and driving, have a conformation that appears to predispose them to OA of the distal hock joints. The hindlimbs are often straight through the hock and stifle, but some horses are sickle hocked and cow hocked. There is a high prevalence of osteochondrosis in Warmbloods, especially of the tarsocrural and stifle joints, which may manifest itself later in the working life of the horse. The headlong dash in recent years for bigger and stronger Warmblood driving horses has in our opinion led to a heavier, less agile horse, often with small feet and limited bone, which cannot help the horse cope with work over the many years that the horse is driven. Foot conformation in some of the carriage breeds, such as the Hackney, Orlov, Gelderlander, and Lipizzaner, can be upright and boxy, which may decrease concussion protection by the foot and increase trauma reflected up the limb. Many of the native breeds or crosses have good conformation and inherent limb soundness, which is reflected in their low level of lameness. The exception to this statement is the pleasure or presentation pony that is worked irregularly and kept at grass in the summer. The overweight (show condition) nature of these ponies and the access to large amounts of grass predispose them to laminitis, which more reflects owner management than suggests inherent unsoundness.

LAMENESS EXAMINATION

Examination of lameness in the driving horse differs little from the standard approach. The major objectives are to decide if the horse is lame, to determine which limb or limbs and which portion or portions of the limb(s) are affected, and to determine a pathological process. This process is complicated in a driving horse, particularly as the horse ages, because of the possibility of old or unimportant lesions and the low-grade and often bilateral nature of some causes of lameness. Further problems are related to intermittent or variable lameness. Identification of lameness is more difficult in a driving horse when being driven, especially lameness in a hindlimb, than in a ridden horse.

The history should consist of typical questions asked before any standard lameness evaluation—for example, how the lameness was first recognized, what the duration of the lameness has been, whether the lameness is worse on hard or soft ground, and whether the horse has responded to any treatments used. In addition, because driving horses are exercising between two poles that are parallel to the ground, straightness is generally fairly easy

for the driver to observe. Is the horse resting one hip on the right or left shaft? Is the horse leaning more on one rein than the other? With pairs and four-in-hand, is one horse taking more of the workload, indicating unwillingness of the other horse to pull an equal load? Have any changes in tack or harness been made? The veterinarian should observe the stance and attitude of the horse, areas of muscle atrophy, limb and foot conformation, and the presence of swellings before assessing the horse moving in hand at the walk and trot on a hard, flat surface. Examination in harness and carriage is rarely useful, because lameness is sometimes less evident while the horse is pulling, rather than moving freely and without restriction on a lunge line. When a driver or trainer feels that the lameness for which the horse is being presented is observed only when in work, that is, driven, seeing the horse in harness then may be necessary. Standard flexion tests of the forelimbs and hindlimbs are useful, but as a horse ages the likelihood of a positive result in an otherwise working, sound horse increases. Exercise on the lunge or in hand on a circle is helpful in horses with bilateral or mild lameness. Exercise on different surfaces (hard and soft) and when possible on a slight incline uphill and downhill can be useful.

Identification of the affected lame limb(s) should be followed by detailed palpation and manipulation of the limb(s), with the limb bearing weight and in a flexed position. Assessment of any swelling by digital palpation and manipulation of the limb(s) to determine whether pain can be elicited can help to differentiate old, clinically insignificant lesions. In older horses distention of fetlock and tarsocrural joint capsules and DFTSs is a common, clinically insignificant finding. Skin scars and areas of fibrosis from previous trauma may further complicate the localization of the site of pain causing lameness. Careful examination of the foot with hoof testers is important. The use of diagnostic analgesia is considered vital to rule out incidental lesions or previously managed chronic problems.

DIAGNOSTIC ANALGESIA

Many of the causes of lameness in driving horses are related to chronic wear-and-tear injuries in one or more joints. Distention of a joint capsule or DFTS can be an incidental finding. Localization of pain by a logical system of regional analgesia is central to our approach to lameness diagnosis and is particularly useful in horses with bilateral or multiple limb lameness, because such an approach allows the effect on the gait of one or more of the lame limbs to be removed, allowing identification of additional lame limb(s). In most horses localization of pain is initially undertaken by a sequence of perineural analgesic techniques beginning distally and moving proximally in a logical manner. In the forelimbs the sequence is palmar digital; palmar (abaxial sesamoid); low palmar and palmar metacarpal (four point); high palmar (subcarpal); and median, ulnar, and musculocutaneous. In the hindlimb the sequence is plantar (abaxial sesamoid); low six point; analgesia of the proximal aspect of the suspensory ligament (SL) (see Chapter 10 for numerous described techniques); intraarticular blocks of either specific joints of the tarsus or suspected stifle joints; and then tibial and fibular (peroneal) nerve blocks. Nerve blocks of the antebrachium or crus are useful when the

veterinarian is uncertain if the lesion is above or below midlimb. Once that has been determined, more specific blocks may be planned proximally or distally as needed. If the veterinarian suspects a particular site, performing an intraarticular block at that site first may be more efficient. It may be necessary to perform intraarticular blocks after perineural analgesia. Sites for intrasynovial analgesia are prepared aseptically (with or without clipping, at the discretion of the veterinarian), and fresh bottles of mepivacaine or bupivacaine, needles, and syringes are used. Gloves are mandatory for intrasynovial techniques. Assessment of response can be difficult in horses with mild or intermittent lameness or when several painful sites exist. The veterinarian should be as certain as possible of the degree of improvement in the lameness, but unfortunately this is sometimes equivocal. In a driving horse the most common intrasynovial structures injected are, in the forelimb, the distal interphalangeal (DIP), proximal interphalangeal (PIP), and metacarpophalangeal joints and the DFTS; and, in the hindlimb, the PIP, metatarsophalangeal, tarsometatarsal (TMT), centrodistal, and tarsocrural joints and the DFTS. Local infiltration of local anesthetic solution around areas of possible damage, such as periosteal reactions and ligament insertions, may be helpful in horses with specific injuries.

IMAGING CONSIDERATIONS

Many causes of lameness in a driving horse, especially in older horses, are related to problems in the distal aspect of the limb and the hock joints. Considerable variation in the radiological appearance of these structures can occur, representing normal anatomical variability, old injuries, incidental findings, or wear and tear. Only by localizing the site of pain to a particular joint by intraarticular analgesia is interpreting these findings possible. Standard radiographic images are obtained. Upper limb injuries are often induced by trauma, are not localized easily by diagnostic analgesia, and are difficult to examine with small x-ray machines. Ultrasonography is particularly useful in examining some of these injuries, not only to differentiate the soft tissue components (e.g., hematoma, muscle injury, edema, and wounds), but also to examine the cortical outline of the bones in the proximal aspect of the limb (shoulder and stifle regions) for evidence of fractures or other damage. Comparison with the opposite limb is helpful in determining what is normal in these areas.

Ultrasonography is essential for examining the DFTS and associated structures and for definitive diagnosis and monitoring of desmitis of the SL or the accessory ligament of the deep digital flexor tendon (ALDDFT). It may also be useful for evaluation of joints for detection of collateral ligament or joint capsule injury and identification of periarticular modeling or articular cartilage damage.

DIFFICULTIES IN DIAGNOSIS

The most difficult problem in diagnosing pain causing lameness in a driving horse is an intermittent, often low-grade lameness that may flare up with increased exercise or competition. Many lame driving horses have bilateral hindlimb problems, often with several sites of pain contributing to lameness. If making progress in these horses

by standard examination techniques is impossible, scintigraphic examination may be useful. The advantages of scintigraphy include the ability to cover many areas of the body (forelimbs and hindlimbs, back and pelvis) at one session, the noninvasive nature of the technique, and its use to monitor healing. The disadvantages include cost, lack of local availability, and lower sensitivity of the technique in localizing chronic sites of inflammation compared with acute injuries. Several sites may be detected as having increased radiopharmaceutical uptake, and other techniques, such as local analgesia, are necessary to assess clinical significance. Making a definitive diagnosis is not always possible, but it is important to treat what is diagnosable or visible and to monitor the horse's progress carefully during convalescence. A reassessment of the horse at regular stages may cast further light on the problem. We frequently tell clients that the best option is to treat what we are able to identify and monitor the progress of such treatment through periodic reassessment. Rest may be easy to accomplish in driving horses because they have a long working life, and in pairs and teams a spare horse may be available to take the lame horse's place, allowing competition to be continued.

A problem occasionally encountered in lameness from harness and carriage use is an abnormal gait, often intermittent, seen only while the horse is working in harness, usually with the carriage. Lameness often is manifested at the collected trot in the forelimb, and an extra lift in the shoulder movement during protraction is apparent. Usually only one forelimb is affected. The horse appears normal at the walk and extended trot, and the problem is not exacerbated by exercise. The actual diagnosis of this condition remains obscure, but one possible theory revolves around the effect of a neck collar on the action of the scapula while the horse is in harness: a mechanical interference. In some horses, changing from a neck collar to a breast band harness appears to stop the problem.

SHOEING

Most driving horses are shod conventionally, with few special techniques or shoes. Many are shod with flat, fullered shoes set rather short and tight at the heels to minimize interference injuries to the horse and the other member(s) of the pair or team. Other reasons for such shoeing given by farriers and owners include minimizing shoe loss in the varying surfaces of the competition and preventing inadvertent removal by the wearer or another horse by standing on the shoe. Short-shoeing a horse, with a tight fit in the heel, exacerbates poor foot conformation, whether the horse has upright, boxy feet or long-toed and low, weak-heeled feet.

The use of studs and occasionally calks, especially in the hind feet, is common in an attempt to increase grip in the marathon phase of competition. In the teams, the wheelers, where the power is mainly delivered, often have studs or calks. If studs have to be used, we prefer to see them put in only for the marathon and, if possible, only for the obstacles. The extra grip studs can give may lead to ligament or joint damage, particularly in the lower limb. The use of studs or calks all the time, especially on hard tracks and roads, increases heel trauma and changes the forces transmitted up the limbs. Unilateral studs and

calks are not acceptable, and their use should be actively discouraged.

TEN MOST COMMON LAMENESS CONDITIONS

A 15-year retrospective study of the clinical practice of one of the authors (KK) led to the formation of the following list of common lameness conditions, in order of incidence. Some variation in incidence occurs from leaders to wheelers in four-in-hand teams and in other countries, such as the United Kingdom.

1. Suspensory desmitis
2. Foot lameness: heel pain, corns, and navicular region pain
3. Distal hock joint pain
4. Exertional rhabdomyolysis
5. Tenosynovitis of the digital flexor tendon sheath
6. Osteoarthritis of the proximal and distal interphalangeal and fetlock joints
7. Stifle lameness
8. Lesions associated with turnout: solar abscesses and bruising, mud fever, rain scald, cracked heels, and kick wounds
9. Interference and traumatic injuries of forelimbs and hindlimbs
10. Desmitis of the accessory ligament of the deep digital flexor tendon and superficial digital flexor tendonitis

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Suspensory Desmitis

Desmitis of the SL, both body and branches, is common, particularly in Amish and Mennonite carriage horses. Seventy percent of the Amish carriage horses are Standardbreds, nearly all of which have raced previously and have preexisting chronic, healed, or healing suspensory desmitis. Forelimbs (80%) and hindlimbs (20%) are affected. Body and branch lesions occur with similar prevalence in forelimbs, but branch injuries predominate in hindlimbs.

Suspensory desmitis may cause an acute-onset, moderate lameness, but often a low-grade insidious lameness is reported by the owner or driver. There is often considerable swelling and inflammation associated with the SL. Horses with branch lesions especially have a positive response to a lower limb flexion test. Diagnosis usually is based on clinical examination and is confirmed by ultrasonography, but in some horses diagnostic analgesia is required to confirm that the SL is the source of pain.

With branch lesions radiological examination of the proximal sesamoid bones (PSBs) and splint bones is required to identify concurrent fractures or sesamoiditis, which influence prognosis. PSB fractures usually are seen in Standardbred horses that have raced previously and were retired with a fracture, pain from which becomes apparent after a second career as an Amish driving horse. Amish and Mennonite horses with a less-than-good prognosis may be culled.

Rest is essential. The duration is determined by improvement in lameness, reduced sensitivity on palpation, and improvement in fiber pattern assessed by ultrasonography. In the initial, acute stages, cold hosing, icing for a few days, and support wrapping are recommended. The combined oral use of dexamethasone and a diuretic is helpful in

decreasing inflammation and filling without masking pain. It is important to provide appropriate palmar or plantar support, and if necessary an egg bar shoe is used to increase the weight-bearing surface.

In horses with the most severe injuries, and in situations in which economics does not play a role in selection of treatment, a more aggressive approach may be considered. Very good results have been obtained with surgical treatment of horses with large core lesions in the body of the SL. After perineural analgesia and localization of the core lesion by ultrasonography, we use a sharpened test bistoury to enter the core lesion with the limb bearing weight. A rigid 18-week slow progressive exercise schedule is then employed. Alternatively, intralesional injections of autologous platelet-rich plasma (PRP) or stem cells can be performed. Several different commercial kits are available for retrieval and harvesting of biological material. We are encouraged by the results to date, but the number of driving horses managed using these techniques is insufficient to report the level of success.

Some clients prefer to turn out a horse with suspensory desmitis rather than adhere to a structured rehabilitation. Our impression is that lesions heal more slowly, often with less acceptable cosmetic results, compared with horses in which controlled exercise is used. Horses with branch injuries are treated conservatively with a long, slow progressive exercise schedule, with periodic ultrasonographic monitoring. Therapeutic ultrasound treatment also is recommended.

Prevention of suspensory desmitis is achieved primarily by selecting well-conformed horses with a good hoof-pastern axis and good feet and continually reassessing hoof balance, the adequacy of heel support, and the angle of the pastern relative to the limb conformation.

Foot Lameness

Foot lameness is common in driving horses and is traumatic, degenerative, or inflammatory. Lameness varies from simple trauma (puncture wounds and bruises) to infectious conditions such as thrush, degenerative conditions such as navicular syndrome, and a host of lesions caused or affected by quality of shoeing.

Carriage horses receive a moderate amount of direct trauma resulting in wounds to the digit. The lack of available prepared and manicured training surfaces often necessitates fitness work on gravel roads and through streams and wooded areas, and solar punctures by stumps or sharp objects are not uncommon. Injuries to the coronary region of horses in pairs and four-in-hand occur when driving conditions are difficult, as in the hazards, when one or more horses may be stepped on by an adjacent horse.

Although wounds of the coronary band are generally obvious, a puncture of the sole may not be readily apparent. A horse with a puncture may or may not be lame at the time of injury. The excitement of competition allows horses to continue without overt signs of discomfort, even with frank injury to the sole. Once back in the stable or sometimes the following day, lameness becomes apparent. Many wounds of the sole and frog are difficult to see, and they can be missed easily. Frog and sole tissue tends to close over the entry site, particularly if the offending object was sharp. If foreign material remains in the foot, severe lameness is usually present. We recommend being very

aggressive with “unroofing” sole or frog puncture sites in horses with severe lameness, because it may be the only way to tell if vital structures are contaminated, and removal of organic material is imperative. Most horses respond well to curettage and soaking in antiseptic solutions, but protracted lameness is usually a sign of infection. Contrast radiology is useful to detect direction and depth of a tract. When a veterinarian cannot determine if vital structures are involved, surgical exploration or magnetic resonance imaging (MRI) examination may be indicated.

Bruises and corns are diagnosed by localizing pain to the sole or heel, evaluating the history, ruling out other causes of foot lameness, and identifying areas of solar discoloration. Treatment for bruising is directed at protecting the sole. In susceptible horses with a chronic tendency toward bruising, use of foot soaks or preferably packing gel with dimethyl sulfoxide with an overwrap frequently is indicated for flare-ups. Horses with corns require changes in shoeing to relieve pressure on the heel and constant monitoring of the heel growth to discourage an underrun, rolled in heel.

Synovitis of the DIP joint occurs as an acute or, less commonly, as a recurrent condition. Effusion of the DIP joint and lameness generally are exacerbated by distal limb flexion. Diagnosis is confirmed by intraarticular analgesia. Treatment consists of phenylbutazone (2 g sid) or flunixin meglumine (500 mg sid) for several days, icing of the digit, and intramuscular administration of a polysulfated glycosaminoglycan (PSGAG), with or without intraarticular administration of hyaluronan or corticosteroids.

Navicular syndrome may be more prevalent in carriage horses of certain breeds. The European Warmbloods, particularly the heavier horses, appear to be at risk. Navicular syndrome is nearly nonexistent in driving ponies. Horses with navicular syndrome have an insidious lameness that usually resolves with palmar digital analgesia. Occasionally a horse has sudden onset of moderate-to-severe lameness without any history of a chronic problem. These horses may have dramatic lesions apparent radiologically without a reasonable explanation for why the lameness occurred suddenly rather than gradually. A critical evaluation of hoof balance is important, and we recommend using bar or egg bar shoes. Very good results have been obtained by intrathecal injection of the navicular bursa with hyaluronan and triamcinolone acetonide (4 to 6 mg) along with improved shoeing. Horses with more pronounced lameness may also be treated with phenylbutazone (1 to 2 g orally [PO] sid).

The greatest number of carriage horses with foot pain fit into a broad category of palmar foot pain (also see Chapter 30). Lengthy drives on hard surfaces result in chronic contusions to the hoof capsule and subsequent lameness. Palmar foot pain often is correlated with the degree of work the horse is undertaking currently and may occur seasonally in susceptible horses. Lameness varies from slight to moderate and is exacerbated by circling on hard ground with the affected limb on the inside of a circle. Hoof tester examination may reveal pain from the medial or lateral sulcus across to that quarter, but a large number of horses have no reaction. Lameness is eliminated by perineural analgesia of the palmar digital nerves. Intraarticular analgesia of the DIP joint and intrathecal analgesia of the navicular bursa ideally should be performed to rule

out these structures as sources of pain. Radiological examination usually is unrewarding.

Assessment of hoof balance and shoeing is necessary, and until any imbalance has been corrected, recommending other therapies is pointless. We have had good results from increasing the length of support or ground surface in the dorsal or palmar direction of the hoof, without any other therapy. Many horse owners do not understand when instructed to move the weight-bearing surface farther palmarly, and they simply raise the heel. Talking directly with the farrier and providing explanatory diagrams to the client are worthwhile. If the heels are too weak or inadequate to allow for corrective trimming, using egg bar shoes until heel growth is adequate may be necessary.

Distal Hock Joint Pain

OA of the distal hock joints is common, particularly in older and larger horses (>10 years old). Many of these horses are not presented by the owner or driver as overtly lame but with a history referring to lack of performance or action, stiffness, back problems, or poor bending. Some horses with OA, especially from teams, are not identified until veterinary inspections at events. Many older driving horses, particularly those in horse driving trials at a high level, have an uneven hindlimb gait, especially when trotted in hand, and have a positive response to upper limb flexion tests. The horse often is said to warm or work into its work (warm out of lameness), and owners do not request investigation. A high percentage of these horses have low-grade OA of the distal hock joints. In some horses acute lameness or gradual worsening of lameness (often described as unilateral lameness by the driver) leads to lameness investigation. In the Warmblood breeds an earlier incidence of this problem has become apparent in recent years, with horses of 5 to 8 years old showing severe OA and even ankylosis of affected joints. Many have poorly conformed and small hocks, and in some OA appears to be a sequela to developmental orthopedic disease in a young, growing horse.

Diagnosis is based on clinical examination, intraarticular analgesia, and radiology. Many horses have bilateral lameness, with one limb worse than the other, and evidence of gluteal muscle atrophy. Poor hock conformation (sickle hocked, straight, or cow hocked) predisposes some horses to OA. Shoe and hoof wear may indicate toe dragging or abnormal lateral breakover. Swelling may be palpable or visible at the seat of spavin. Tarsocrural joint distention is a common incidental finding, but it may indicate proximal intertarsal (talocalcaneal-centroquartal) joint involvement. The gait often is characterized by reduced foot flight arc and hock flexion, leading to toe dragging, and adduction of the limb medially underneath the body to land and then breakover laterally. On the lunge, lameness of the inside hindlimb may be worse, with shortening of the cranial phase of the stride and a tendency to fall toward the handler. Bilateral lameness is common, although one limb is often worse, leading to a choppy or stilted gait.

Flexion tests of the upper hindlimb are often positive bilaterally, but the response varies enormously depending on the stage and extent of the disease and the individual horse. Positive flexion test results in the hindlimbs of older driving horses are common, even in the absence of lameness.

Initially, lameness can be localized to the hock region using perineural analgesia, although intraarticular analgesia is more specific. Previously the centrodistal and TMT joints were blocked separately, but more recently only the TMT is blocked, on the basis of recent research confirming the high rate of diffusion of mepivacaine between the two joints.

A poor correlation exists between the degree of lameness and the extent of radiological abnormalities. Scintigraphic examination may be indicated in the absence of radiological abnormalities.

Treatment depends on a variety of factors including the degree of lameness, other concurrent causes of lameness (e.g., back problems), the type and extent of radiological abnormalities, the age of the horse, the level of work, the competition undertaken, the time and cost constraints, and the response to previous treatment. Conservative treatments often are used when financial constraints exist, when lameness is mild, or when radiologically the disease is advanced, or simply to assess the effects of treatment before more radical therapy is considered. Surgical treatments involve the willingness of the owner to make the financial investment and subject the horse to the risk of general anesthesia. We usually assess all aspects on an individual basis before embarking on a standard treatment plan, involving three monthly clinical and radiological examinations.

In general, because of the low-grade and chronic nature of the complaint in driving horses, a horse initially may be treated conservatively with corrective shoeing (graduated toe heel shoe, rolled at the toe, with or without lateral extension), a controlled graduated exercise program (up to 90 minutes) placing an emphasis on walking and trotting in a straight line (ridden or driven), and oral medication with variable levels of nonsteroidal antiinflammatory drugs (NSAIDs) (usually phenylbutazone) to control pain and encourage a more normal action. Many driving horses make considerable clinical progress with this regimen, but few high-level driving trial horses are able to return to competition quickly. Resolution of lameness may take up to 18 months and in some horses never happens if conservative treatments are used. Predicting the course of the disease and ultimate result in any one horse is difficult early and requires consideration of all the clinical and radiological findings. Many horses improve, but they do not become sound and have minimal progression of radiological abnormalities over 6 to 12 months. Horses with more obvious lameness, or those that are unable to cope with exercise with orally administered phenylbutazone, may be candidates for intraarticular injections with long-acting corticosteroid preparations (10 mg triamcinolone acetonide or 40 mg methylprednisolone acetate per joint). This may result in improvement for 3 to 6 months, and repeated injection usually is required. The use of NSAIDs or corticosteroids is not allowed in official competitions, and drugs must be withdrawn according to the manufacturers' recommendations before any competition. The use of tiludronate has increased with mixed results. Pentosan polysulfate (Cartrophen) is used by some clinicians, but there is controversy over its efficacy, and the drug is not licensed for use in the horse in Europe.

Arthrodesis is used in horses that fail to respond to conservative or intraarticular treatment or are in too much

pain to achieve ankylosis by exercise, and when time to return to performance soundness is important. In horses with minimal radiological changes, intraarticular injection of sodium monoiodoacetate is performed using general anesthesia. In horses with more advanced radiological abnormalities or those in which monoiodoacetate has failed to achieve ankylosis, surgical treatment using three drill holes is used in each joint. Controlled exercise post-operatively is essential for success with either treatment. Although many driving horses with OA of the distal tarsal joints are useable with treatment, complete resolution of lameness is unusual.

Exertional Rhabdomyolysis

Carriage horses have isolated episodes of tying up during competition or strenuous exercise, and this is a true exertional rhabdomyolysis. Competition horses may develop mild signs of muscle stiffness affecting the hindquarters, during or at the conclusion of an exertional session, such as the marathon. The condition may become apparent in the 10-minute box, during the formal veterinary examination section, or before the marathon course. Clinical signs are invariably subtle and may be interpreted as fatigue by an inexperienced competitor. Affected horses should be withdrawn from the competition to avoid further skeletal muscle damage. Treatment should include administering antiinflammatory drugs and low doses of acepromazine (5 to 25 mg total dose) and ensuring adequate hydration. Horses should not be walked out of the stiffness and should be moved by trailer from the 10-minute box to a treatment stall.

To prevent further episodes, the feeding up to and including a competition and a horse's fitness program should be evaluated and amended as necessary. Teaching drivers how to assess a horse's fitness by measurement of temperature and pulse and respiratory rates on the stress days of training sessions is particularly valuable.

Acute, severe rhabdomyolysis (tying up) also occurs in horses driven by the Amish and Mennonites. These are frequently emergency situations. Horses have true, severe exertional rhabdomyolysis and are often in recumbency when examined. The clinical signs in nonrecumbent horses are extreme muscle stiffness and swelling over the topline and gluteal muscle groups, increased heart rate, sweating, and coliclike symptoms. The history is consistent: the horse became stiff while being driven, but the driver needed to continue to a destination and may have been driven another 1 to 15 miles [1.6 to 24 Km]. The condition in colloquial Amish terminology is referred to as *kidney shot*.

Rehydration and controlling pain and shock are imperative. Tranquilizers are particularly helpful, and measurement of packed cell volume and total protein concentration is useful for monitoring hydration. Measurement of creatine kinase may be useful prognostically in recumbent horses, although the initial response to treatment and the ability to get the horse on its feet are primary factors in determining whether the horse can be saved. Creatine kinase concentrations are often 400,000 to 800,000 IU/L (normal 130 to 400 IU/L), and we have treated horses successfully with levels up to 600,000 IU/L. Without prompt emergency attention, nearly all of the more severely affected horses die or are ultimately humanely destroyed. Most horses that remain recumbent after 24 hours are lost.

Horses are viewed by Amish farmers as utilitarian and necessary for transportation, and prevention of fatal exertional rhabdomyolysis is not necessarily easy. Owners should be advised of the need to match exercise with the intake of concentrates. If possible, the horse's entire body can be clipped if the onset of summer or warm weather is sudden or the winter coat is still present. Clipping can be done using a gas-powered generator for the clippers. Clipped horses have less risk of severe dehydration, and a clipped horse apparently is less prone to rhabdomyolysis than a hirsute horse.

Tenosynovitis of the Digital Flexor Tendon Sheath

Tenosynovitis of the DFTS is a common cause of acute hindlimb lameness. Often extreme swelling of the DFTS occurs and is turgid and firm, which contrasts to chronic, benign distention of the DFTS in which fluid in an overly stretched sheath can be balloted from side to side.

With horses with acute tenosynovitis there is a substantial response to lower limb flexion, and in some horses (5%) a non-weight-bearing lameness develops. Using perineural analgesia is unnecessary, but intrathecal analgesia using 6 to 10 mL of mepivacaine can be used to confirm the source of pain. Synoviocentesis is best performed distal to the fetlock and is facilitated by applying a disposable elastic bandage around the distal metatarsal region to push the fluid into the distal outpouching of the sheath on the plantar aspect of the pastern (Figure 124-1). Once

the sheath has been entered, an assistant cuts off the bandage, and local anesthetic solution is injected.

Radiological examination is usually negative, but is necessary to be certain that no unexpected lesion is missed. Ultrasonographic examination is essential to determine if tenosynovitis is associated with a lesion of the deep digital flexor tendon (DDFT), which requires a longer convalescence, and horses have a more guarded prognosis than those with primary tenosynovitis.

Treatment is based on reducing inflammation and controlling exercise. Uncontrolled turnout results in prolonged healing, and stall rest followed by walking in hand is preferable. A horse with an acute injury is treated with icing for 40 minutes twice a day, for 2 to 3 days, and orally administered NSAIDs. Intrathecally administered hyaluronan is beneficial. Caution should be exercised in the use of corticosteroids, which may provide temporary relief and often give the client a false sense of security regarding the rate of healing. Isoflupredone acetate is recommended, is short acting, and may control the acute flare-up without having any long-term effect that makes monitoring progress difficult. Methylprednisolone acetate lasts at least twice as long and may predispose the horse to develop dystrophic mineralization in the sheath. We have had better long-term results with conservative medical management than with surgical treatment by desmotomy of the plantar annular ligament.

Prevention of tenosynovitis and tears of the DDFT is difficult, because most injuries are acute and unforeseeable,

Fig. 124-1 • **A**, Application of a pressure bandage isolates fluid in the distal, plantar outpouching of the digital flexor tendon sheath, facilitating synoviocentesis. **B**, An assistant cuts the compression bandage during injection.

occurring during strenuous exercise. A team horse previously used as a wheeler may be better placed as a leader. The foot should be kept well balanced, with a full-fitting shoe providing adequate plantar support.

Chronic Osteoarthritis of the Lower Limb Joints

Many driving horses develop chronic OA of the DIP, PIP, and metacarpophalangeal joints as a result of wear and tear because of the work they undertake, the length of time they are used, and other factors such as conformation, foot shape, and shoeing. Radiological examination of these joints, especially in the hindlimbs and in larger horses, often reveals a variety of intraarticular and periarticular abnormalities that may be associated with lameness. Older driving horses often live with low-grade hindlimb gait abnormalities associated with low-grade joint pain. This low-grade, chronic, and often multiple leg or multiple joint pain can be exacerbated by excessive or different exercise regimens, leading to acute flare-ups, increased lameness (often unilateral), joint flexion pain, periarticular heat, and joint swelling. Radiographs obtained at this time reveal little more than the preexisting abnormalities. Intraarticular analgesia may be essential to localize the pain causing lameness, but multiple limb and joint involvement can make localization difficult. Nuclear scintigraphy may be helpful, but it is expensive, and often it is used only after early treatment has proved unsuccessful.

Treatment of horses with acute flare-ups of OA involves cold therapy such as cold hosing or ice packs, compression bandaging, systemic NSAIDs, topical applications of various antiinflammatory substances, and intraarticular or systemic medications such as corticosteroids, hyaluronan, interleukin-1 receptor antagonist protein (IRAP), and PSGAGs. Rest and a controlled, graduated return to exercise are important. Management of horses with chronic OA involves a careful review and possible modification of the horse's work program, judicious use of NSAIDs, physiotherapy techniques such as laser or ultrasound treatment, and systemic medication with hyaluronan or PSGAGs. The prognosis varies enormously depending on the severity and extent of the problem, the way in which the individual horse responds to pain, and the level of work required to keep the horse sound and competing. In many horses, if the hindlimbs are affected and especially if the condition is bilateral and the horse is part of a pair or team, then the chronic low-level lameness is not observed, is undiagnosed, or is ignored. An acute flare-up may lead to recognition of the problem and diagnosis. Prognosis for horses with the first acute flare-up is reasonable, but those with further occurrences warrant more aggressive management, which if unsuccessful worsens the overall prognosis.

Stifle Lameness

A definitive diagnosis of the cause of stifle pain in driving horses is often difficult to determine. Most horses with stifle lameness are wheelers of a four-in-hand or one of a pair. It is generally accepted that wheelers supply 60% of the workload in pulling, which may affect the incidence of stifle lameness. Lameness is usually acute in onset and unilateral, with no stifle effusion or other localizing clinical signs. Stifle flexion may cause more obvious accentuation of lameness than other hindlimb flexion tests. Lameness is improved by intraarticular analgesia.

Radiographs uniformly are negative. Ultrasonographic examination may sometimes reveal a lesion, but in more than 80% of horses no cause of pain can be identified. However, with digital ultrasonographic imaging and improved operator skill the likelihood of establishing a diagnosis may improve. Arthroscopic exploration may be warranted, but this is expensive, and only a limited part of the stifle can be assessed. The prognosis generally is guarded for horses with a known meniscal or cruciate ligament injury and for those without a specific diagnosis. The best results have been achieved after intraarticular treatment with hyaluronan, combined with systemic administration of PSGAG and rest or rigidly controlled exercise, walking in hand.

We recommend that horses not resume work until 60 days after complete resolution of lameness *and* when they no longer manifest a positive response to stifle flexion.

Direct Trauma

Traumatic injuries to the limbs and body of a driving horse are common.

Interference Injuries

Distal limb lacerations of varying severity are common, especially in horses that are part of a team, particularly in combined driving, and are caused by overreaching (forelimbs) or by interference from other horses. The most common lesions involve the heel and coronary band (Figure 124-2), although wounds to the midpastern and distal palmar (plantar) aspect of the metacarpal (metatarsal)

Fig. 124-2 • A severe heel bulb laceration sustained by a driving horse during a team competition, probably caused by interference from another horse.

region occur frequently. Many wounds are superficial and consist only of contaminated skin, but it is essential to check for injury to the digital flexor tendons and the DFTs, joint integrity, and damage to the coronary band. The horse should be restrained properly, the affected area clipped and vigorously cleaned, and the damage assessed before medical or surgical treatment is initiated. In some horses detailed examination using digital palpation with sterile gloves, radiography, ultrasonography, and even surgical exploration may be necessary. Early and aggressive treatment may improve the prognosis considerably in the short and long term.

Injuries to the Brisket, Lower Neck, Antebrachium, Stifle, and Crus

Injuries usually occur during the marathon phase of driving trials, especially in the obstacles, or after runaways and accidents in any driven horse. The tendency of some drivers in combined driving in recent years to drive the carriage as a battering ram through the obstacles has increased the incidence of these injuries. Skin lesions occur, especially in the brisket and caudal aspect of the neck and upper forearm regions, and can range from full-thickness lacerations to mild hair loss and deeper bruising (Figure 124-3). In some horses little is visible externally except

Fig. 124-3 • A severe traumatic injury to the upper forelimb and brisket regions caused by a collision with an obstacle in the marathon.

mild swelling to suggest the site of impact. Stiffness or lameness often develops several hours later. Severe trauma, particularly involving broken shafts or obstacles, can lead to life-threatening injuries to the chest, abdomen, or vital vascular structures.

The injured area should be examined carefully, particularly when lacerations are present. In these, thorough lavage and cleaning, followed by digital exploration using sterile gloves to assess for additional deeper damage, are essential. Surgical repair may be necessary. Horses with blunt soft tissue damage and bruising benefit from light walking in hand, cold therapy, topical and systemic anti-inflammatory medication, and physiotherapy techniques.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT is a common cause of forelimb lameness. Older horses, including ponies, are more likely to be affected, and injury can occur at exercise or during turnout. Onset is usually acute, with unilateral forelimb lameness occurring during or immediately after exercise. Swelling of the ALDDFT occurs with edematous swelling of the surrounding soft tissues. In horses with severe desmitis, periligamentous hemorrhage can occur. Palpable pain is rare, but heat usually is apparent.

Ultrasonographic examination is used to determine the extent of injury. Diffuse lesions are more common than focal core lesions. Damage to other tendon structures is uncommon, but adhesions to the superficial digital flexor tendon (SDFT) or DDFT do occur, particularly in horses with chronic recurrent injuries.

Treatment of horses with acute injuries includes cold therapy, compression bandaging, box rest, and topical or systemic anti-inflammatory medications. We regularly recommend the use of systemic PSGAG therapy and therapeutic ultrasound physiotherapy from 7 days after injury. Graduated walking in hand is encouraged from 7 days after injury, increasing in duration up until 12 weeks, when limited free exercise is allowed. Ultrasonography is essential to determine when healing is sufficient to allow exercise to begin. A total convalescent period of 6 to 15 months may be required. Some injuries, particularly in older horses, do not heal satisfactorily. Occasionally horses with chronic injuries with adhesions have been treated by desmotomy of the ALDDFT, but the prognosis for return to full soundness is guarded. Recently a small number of horses with severe injuries have been treated with PRP, but it is too early to evaluate success.

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis is not common in a driving horse, although the condition is seen occasionally as a flare-up of a lesion sustained previously in another discipline, or in wheelers when the going during the marathon phase has been soft and deep. Most lesions are in the distal half of the metacarpal region and are generally mild. Diagnosis is based on clinical and ultrasonographic examinations. The prognosis for return to full work as a driving horse is generally good, because most of the injuries are mild and the type of work to be undertaken is usually slow.

| Chapter 125

Lameness in Draft Horses

Dallas O. Goble

The draft horse today enjoys a position in the world far different from when it was considered primarily a work animal. Draft horses supplied power for farming, transportation of commodities, lumbering, road building, and all such tasks until the 1930s, when the gasoline engine essentially replaced the horse. Isolated areas still continued to use the draft horse for farming and some lumbering activities until the early 1940s. After this period, draft horses were used primarily for specialty areas such as movie production, theme parks, parades, and frontier celebrations. But in some communities, religion and family tradition mandated the continual use of draft horses as a power source for farming. During the 1950s and 1960s, draft horses decreased in numbers in the United States, and subsequently the genetic pool was decreased. Draft horses started gaining popularity in the late 1970s and early 1980s and have once again become a popular member of the horse industry.

Draft horses today are different from those of the early 1900s. They perform different functions and are owned for a different purpose. Owning a draft horse is far more likely to be simply a hobby than an economic part of the family income. Many horses are used strictly for show purposes in classes such as halter, fine harness, and equitation, or for parades and advertising. Draft horses are used for trail riding, pleasure riding, fox hunting (often crossbred with Thoroughbreds), and other pleasure uses. In some mountain areas where selective lumbering of individual trees is undertaken, draft horses are still used today. With a resurgence of interest in mules, draft horse mares often are used in the breeding programs. Draft horses frequently are crossed with Thoroughbreds to change the genetic pool for the breeding of large hunter, jumper, and Three Day Event horses. Pulling contests are popular in certain areas and represent an additional use of the modern-day draft horse.

MODERN-DAY DRAFT HORSES

The most important physical change of the modern-day draft horse is its size. In many modern breeding operations, size is the main criterion used for selection. When draft horses were used predominantly as working horses, the average weight was 680 to 775 kg (1500 to 1700 lb) and the average height was 1.6 to 1.7 m (15.5 to 17 hands). This size was optimal for the multipurpose activities these horses performed on most farms and ranches. They pulled the plow, mowed and raked hay, helped round up cattle, and often took the family to church on Sunday. Draft horses today are more frequently in the range of 820 to 1000 kg (1800 to 2200 lb) and measure 1.8 to 2 m (17.5 to 19.5 hands) in height. As a result of selection based on size as the dominant characteristic, conformation and quality

have suffered in some respects. Distribution of lameness also has changed. Foot size and quality have not increased proportionately with body size and weight. Osteoarthritis (OA) is common in draft horses and likely is related to body size rather than the use of the horse. Hybrid vigor, once thought to be advantageous, has decreased by using the practice of line breeding for selected traits. The large size of a draft horse sometimes misleads one to think the horse can withstand greater stress and disease than can light horses, but I have not found this to be true. Draft horses may not recover as well as light horses with the same injury or disease. Because draft horses have a tendency to be stoic, recognizing a severe problem early in the disease process may be difficult. This tendency may cause a costly delay in diagnosis and management. The physical size of draft horses today has hindered veterinary care and treatment. Veterinarians tend to be unsure of drug dosage and appropriate treatment schedules because of the large body size. Many hobby horse owners do not have facilities adequate to handle a 1000-kg horse and may not be knowledgeable in draft horse care. Draft horses are not always well trained or easy to handle, and owners are sometimes unable to lend assistance when needed. These facts have curtailed the interest of many practicing veterinarians who have difficulty rationalizing being stepped on by a 1000-kg draft horse as fun. In addition, finding high-quality foot care for a draft horse is sometimes difficult, because most farriers are experienced with light horses. Farriers feel similar to veterinarians: "Why hold up a 1000-kg horse twice as long as needed to hold up a 500-kg horse?" In addition, farriers who shoe draft horses have to stock nails, shoes, and bar stock often on special order or low-volume items, a fact that dramatically increases overhead expenses. Thankfully, some veterinarians and farriers are willing to treat and specialize in draft horse care.

The following discussion related to draft horse lameness reflects my personal clinical experiences and not necessarily what may be in the equine literature. Lameness distribution may vary from my observations depending on the use, location, individual draft breed studied, or other factors associated with different populations of horses.

LAMENESS EXAMINATION

Diagnosis and management of lameness in a draft horse may seem more intimidating simply because of the large size of the horse and the infrequency with which requests are made for examination compared with light horses. In reality, draft horses experience the same problems as do light horses, although the distribution is different, and the principles of diagnosis and management are the same. The lameness examination is the same as in light horses, and any deficiency of hands-on experience can be overcome by a systematic and thorough examination. Palpation of peripheral nerves (palmar and plantar digital nerves, in particular) can be difficult because of thick skin and hair, and veterinarians are sometimes reluctant to attempt peri-neural or intraarticular blocks. The anatomy is the same, but the ability to palpate the nerves is diminished by these factors and also by subcutaneous thickening that some draft horses develop in the lower part of the limb.

Draft horse lameness diagnosis and management lagged behind those of light horses for many years. First, as long as the horse could still accomplish farm work, less concern was shown for a horse that limped slightly. Possibly the person behind the plow or cultivator also limped and accepted it as part of doing the job. Second, economic considerations were a major factor in the farming operation. This does not reflect necessarily a lack of care, but it was simply an accepted part of working in that day and time. But today, draft horses are afforded the same concerns and care given to the light horse, and only modification of most treatment protocols needs to be made.

Detailed description of the lameness examination can be found in earlier chapters. Special attention should be paid to several critical points, however. Draft horses are more stoic than light horses, and as a result lameness may be advanced when first recognized. For example, draft horses with OA of the proximal interphalangeal (PIP) or distal interphalangeal (DIP) joints may have severe radiological changes, but the owner may report that the horse only recently showed signs of lameness. Granted, many owners are inexperienced, but even the experienced owner may not recognize a problem until it is well advanced. This can be explained partially by the fact that a draft horse often is used at a gait (walk) that makes lameness less obvious, and the horse frequently is hitched with one to seven additional horses, and an individual horse's problems are less discernible in a group.

When possible, observing the horse at a walk and trot on soft and hard surfaces is useful. Hoof tester examination, in my experience, is less reliable in draft horses than in light horses. Small hoof testers are of questionable value. Even with long-handled hoof testers, it is difficult to apply enough pressure to produce a positive response. Foot lameness should be suspected if a horse shows grade 1 of 5 lameness on soft footing but grade 3 of 5 lameness on a hard surface. The examination always should include backing the horse at least two or three times and observing the horse at the walk and trot in a circle and in tight turns. Sometimes conditions such as shivers, stringhalt, or intermittent upward fixation of the patella are seen only during these maneuvers.

Lower limb flexion tests are less rewarding in draft horses than in light horses. It is difficult to apply sufficient pressure during the flexion test to accentuate pain in this region. A draft horse may be less willing to trot after a flexion test, making it difficult to determine a true positive response. Most light horses will trot after flexion, even when the reaction is highly positive, but a draft horse will not trot off as readily without strong urging. In addition, draft horses often are not accustomed to being trotted in hand routinely. Hindlimb upper limb flexion tests in a draft horse are a more reliable indicator of hindlimb lameness than in a light horse.

I prefer to perform diagnostic analgesia with the horse in a standing position, rather than having an assistant elevate the limb. This is especially true when attempting palmar digital nerve blocks or palmar nerve blocks at the base of the PSBs. Palpating anatomical landmarks in this area when a draft horse is bearing weight is easier than when the limb is elevated. To maintain the limb in an elevated position or to restrain the limb in this position can be difficult. Adequate restraint usually can be achieved by the application of a nose twitch.

TEN MOST COMMON LAMENESS PROBLEMS

Over several years I evaluated 745 draft horses admitted with a chief complaint of lameness. The following list shows the top 10 lameness conditions that I observed in order of decreasing frequency (33 horses had other problems):

1. Foot lameness (abscess, hoof cracks, laminitis, and sidebone) 260
2. Tarsal lameness (osteoarthritis, bog spavin, and osteochondrosis) 207
3. Splints 84
4. Tendonitis and suspensory desmitis 45
5. Osteoarthritis of the distal interphalangeal or proximal interphalangeal joints 44
6. Fetlock lameness (sesamoiditis, osteoarthritis, and osteochondrosis) 23
7. Thoroughpin 18
8. Carpal lameness (traumatic or infectious carpalitis) 13
9. Stifle lameness (traumatic, upper fixation of the patella; osteochondrosis) 10
10. Myopathy 8

LAMENESS COMMON TO THE FORELIMB AND HINDLIMB

Foot

The foot is the most common source of pain causing lameness in draft horses. A thorough and complete examination of the foot is paramount to diagnosis and management of lameness. Hoof quality and conformation have suffered in modern-day breeding selection, and as a result we tend to have large horses that are supported on feet that lack hoof size and quality. I suggest that breeders of draft horses give strong consideration to hoof conformation when making critical selections for breeding programs.

Subsolar Abscess

The most common cause of foot lameness in a draft horse is a subsolar abscess, a problem most frequently encountered in a forelimb. The high incidence of subsolar abscess formation in draft horses can be related to several factors. First, obtaining consistent farrier care may be difficult in many locations, and foot care may be neglected. Second, draft horses often have poor hoof quality and easily develop hoof cracks or severely chipped and broken hoof walls. Clydesdales have particularly poor hoof quality. Many draft horses have dropped soles, predisposing them to bruising and subsolar abscess formation.

A pair of large, good-quality hoof testers provides the simplest method of determining the location of the abscess. Tapping the hoof wall or sole with a hammer (or the hoof testers) can help locate the abscessed area. In horses that recently have been shod or reset, each nail should be examined. An abscess associated with a nail usually develops 5 to 11 days after shoeing. Hoof cracks causing instability of the hoof capsule can cause lameness even though the area of abscessation may have resolved. If a foreign body is lodged in the hoof (nail, glass, or other penetrating object), a fistulogram (contrast radiograph) should be performed. A subsolar abscess can become a life-threatening problem

if osteitis of the distal phalanx develops or penetration of the DIP joint, deep digital flexor tendon (DDFT), or navicular bursa occurs. Proper diagnosis is mandatory; otherwise, the long-term prognosis becomes worse.

Once the abscess is located, the sole should be pared with caution, especially if the horse has a dropped sole or has a concomitant full-thickness hoof wall crack. Overzealous sole paring may result in extensive mechanical damage to laminae and loss of hoof wall strength. Adequate drainage is paramount, but removing a large amount of sole is not necessary, even when substantial undermining has occurred. In draft horses, it is important to err toward a conservative approach, at least initially. Thorough flushing of the foot with povidone-iodine or chlorhexidine diacetate solution should be done at least once a day for 3 days or until the drainage has stopped. The foot can be soaked in a saturated solution of magnesium sulfate for 3 to 5 days to reduce inflammation and to aid in drainage. Finding a soak boot large enough for draft horse feet at a reasonable cost is difficult, and I have found an easy solution by using a 1 m length of truck tire inner tubing. The tubing is slipped half its length over the foot, and then up the leg, with the remaining half doubled back up the leg and secured in place by a wrap of choice (Figure 125-1). The tube then can be filled with the soak solution. Draft horses with an uncomplicated subsolar abscess do not need to be treated with systemic antibiotics. However, if cellulitis of the coronary band and pastern region is present, the administration of antibiotics is indicated. Trimethoprim-sulfadiazine (15 mg/kg orally [PO] bid) or ceftiofur sodium (1 mg/kg intravenously [IV] bid or intramuscularly [IM]) is my usual choice. Judicious use of nonsteroidal antiinflammatory drugs (NSAIDs) is indicated, but these drugs should

Fig. 125-1 • Draft horse with rubber inner tube in place and used as a soak boot for a foot abscess.

not be used for extended periods of time or at levels that may mask a more serious problem. Phenylbutazone, 4 g PO or 2 g IV, on the first day is sufficient. Thereafter, 3 g and then 1 g are given orally on the second and third days, respectively. A tetanus booster should be administered if the horse's vaccination status is not current or is unknown.

If the horse's condition is not improved in 3 days, the horse should be reexamined. Radiography and positive contrast fistulography should be performed. A fistulogram is performed using contrast material administered through a Foley catheter. The foot should be held off the ground when contrast medium is infused and should be held up for 2 minutes thereafter. The foot is then placed in a weight-bearing position, and radiographs are obtained immediately. During weight bearing, a fistulous tract often is closed by soft tissue compression. If deeper structures are involved (DIP joint, DDFT, distal phalanx, or navicular bursa), an extensive treatment program is initiated, including bacterial cultures, surgical drainage or curettage, lavage of the affected area, and the administration of broad-spectrum intravenous antibiotics. The initial antibiotic treatment usually includes 20,000 IU of potassium penicillin per kilogram four times a day and 6.6 mg of gentamicin per kilogram once a day. Bacterial culture and susceptibility testing results may require changing the antibiotic regimen.

Hoof Wall Cracks

Forelimb hoof wall cracks were found in 67% of the 260 draft horses examined for lameness of the foot, although not all were the primary cause of the horse's current problem. Full-thickness hoof wall cracks need to be stabilized when they cause lameness. The crack should be cleaned carefully and curetted, and normal hoof wall should be present on each side of the defect. The technique of dovetailing may provide additional support if hoof repair material is used. Dovetailing is accomplished most easily using a 1-cm ($\frac{3}{8}$ -inch) round burr on an electric drill and undermining the hoof wall at about a 45-degree angle, leaving a shelf of hoof wall down to the white line on each side of the defect for the full length of the crack. This provides additional surface area for a stronger repair and reduces the likelihood that the repair material will come out. Care must be exercised to avoid damage to the sensitive laminae or to create bleeding during this procedure because these may predispose to abscess formation beneath the repair material. If the horse is initially unshod, a shoe with clips may be sufficient to provide support and to immobilize the defect. Radiator hose clamps and 1-cm long, No. 8 metal screws can be used to stabilize the crack. Because infection is often a problem, the radiator clamp method can be used initially, when filling the defect with repair material is contraindicated. Antibiotic-impregnated repair material has been used, but my success with this material in draft horses has been limited, and my preferred method is a shoe and the radiator clamp and screw combination. It is important to have at least two screws through each piece of clamp and on each side of the defect to add stability. The top clamp should be placed at the proximal limit of the crack. I generally space the clamps 1.9 cm ($\frac{3}{4}$ inch) apart, and the number of clamps needed depends on the length, depth, and amount of instability in the crack and on the size of radiator clamp used. The clamps are removed as the defect grows and are replaced if broken. The clamps must

be tightened carefully, because lameness from laminar pain will be worse if the clamps are too tight. This problem is corrected by adjusting the clamp with a screwdriver.

Laminitis

Laminitis in draft horses is a serious lameness condition, and prognosis for complete resolution often is guarded to unfavorable. Regardless of the cause (e.g., grain overload, colitis, metritis, retained placenta, toxemia), once the pathophysiological process of laminitis is in motion, the end results are similar. The solution to the primary cause often is solved more easily than the secondary problem of laminitis. This is especially true in mares with retained placenta, in which the retained placenta and metritis are solved easily, but secondary complications may be devastating. Many of these mares develop severe laminitis with distal displacement (sinking) of the distal phalanx.

I would like to contrast my observations of draft horses with laminitis to similar conditions in light horses. Laminitis carries a more guarded or unfavorable prognosis in draft horses for many reasons. Our ability to manage secondary problems is less satisfactory in draft horses. Size, when we consider a 1000-kg as opposed to a 400- to 500-kg horse, is the most important factor. Slings are seldom big enough, and hoists or hoist support systems may not be available to lift a draft horse safely. Locating a farrier who will work on a chronically lame draft horse and forge therapeutic shoes on a consistent basis is often difficult. Management of draft horses with myositis, decubital ulcers, infections, pneumonia, and other secondary complications is more difficult and costly. The owner must be informed clearly of cost, and a dedicated team (owner, farrier, and veterinarian) must be assembled to manage these complications. I generally tell clients that at least 1 year will pass before the horse's level of function can be assessed reasonably.

Classification of laminitis is confusing, and I make little attempt to classify laminitis based on chronicity or by using the Obel grading system (see Chapter 34). Regardless of classification used, prognosis for return to function is poor if lameness is severe and persists for longer than 10 days with intensive treatment. In my experience, two major differences exist between draft horses and light horses. First, draft horses develop laminitis more frequently and severely in the hindlimbs. Second, draft horses are more likely to develop distal displacement (sinking) of the distal phalanx once laminitis occurs (Figure 125-2). This latter difference may be related to hoof quality or hoof care in general and the important role that body weight plays in causing distal displacement. In addition, shoeing methods that flair the hoof wall simply to give the impression of a large foot weaken laminar support. Distal displacement can occur in horses with traumatic laminitis without a traditional laminitic episode. Traumatic laminitis and sinking can occur unilaterally, only to then occur weeks to months later in the opposite foot. Traumatic laminitis caused by incorrect shoeing can be reduced greatly or eliminated when proper shoeing is provided on a regular basis.

Diagnosis of laminitis is not difficult except in draft horses with traumatic laminitis that is slowly progressive, without an acute episode typically seen with laminitis in a light horse. These horses often have a dropped sole (including the frog in many horses), with the entire sole at a level below the hoof wall. Increased digital pulse amplitudes may be missed easily in a draft horse, but hoof tester sensitivity and abnormal stance are important clinical signs. Initial and follow-up radiographs should always be obtained.

Management of draft horses with laminitis is similar to that of light horses, but some precautions need to be taken.

Fig. 125-2 • Lateromedial radiographic image of the front foot of a draft horse mare that had developed laminitis in all four limbs within 24 hours of foaling and retention of the placenta. The radiographic image was obtained 10 days after foaling. The proximal end of the radiodense marker on the dorsal hoof wall is at the level of the coronary band. Both extensive sinking and rotation of the distal phalanx have occurred. Note also the broad radiolucent line in the dorsal hoof wall, the result of laminar necrosis. The mare was managed until the foal was weaned, but humane destruction was ultimately necessary.

Pain amelioration is important but often difficult to achieve. Clydesdales, for instance, are susceptible to gastric and colonic ulcers when treated with phenylbutazone. The Belgian horses that I have treated with phenylbutazone seem less susceptible to ulcers than do Clydesdales. In Clydesdales I seldom if ever administer more than 4 g phenylbutazone PO daily or 3 g IV daily, unless no other alternative is available. The dose should be lowered as quickly as possible, and the high dose should be maintained for a maximum of 5 to 7 days. Although this dose is low based on milligrams per kilogram, Clydesdales have many gastrointestinal complications with higher doses. Flunixin meglumine, meclofenamic acid, and other NSAIDs can be used, but phenylbutazone is the most frequently used and cost-effective drug. Butorphanol tartrate (0.01 to 0.02 mg/kg) can be used with phenylbutazone to lower the necessary dose of NSAIDs. Butorphanol tartrate alone is not a satisfactory analgesic for draft horses with laminitis, but it is useful with NSAIDs, and can be administered three or four times each day.

To provide frog support initially, I use pieces of rubber stall matting, 1.9 cm ($\frac{3}{4}$ inch) thick. The matting is cut to fit the foot and frog and then secured with fiberglass cast material. To increase thickness, two rubber pads can be glued together. To raise the heel in draft horses with acute laminitis, a hand grinder can be used to make a wedge pad from the rubber mat. I believe raising the heel helps to reduce pain and rotation of the distal phalanx. The heel should be elevated 10 to 14 degrees. The single most important factor in draft horses with laminitis is to avoid excessive paring of the sole. Paring the sole away to make it look like a normal sole is putting the curse of death on draft horses with laminitis. This practice removes natural protection from rotation or sinking, and the sole supports the foot better than anything we can apply externally.

Radical hoof wall resection should be avoided. I recall two horses that were referred after complete dorsal hoof wall resection. In both horses the remaining hoof wall lacked strength, and although one horse was shod and the other was unshod, the distal phalanx rotated and sank through the remaining hoof wall in both horses, which were euthanized. If hoof wall resection is indicated, a shoe with side or quarter clips is applied *before* the procedure is performed. The entire hoof wall should not be removed at one time, but resection should be staged over 2 to 3 weeks. If the hoof wall spreads and crowding of the side clips occurs or if further rotation or sinking of the distal phalanx is observed, any further resection is delayed. The coronary band should be assessed each day for signs of sinking (depression at the top of the coronary band). Radiography is helpful but does not replace careful physical examination. Horses with subsolar abscesses are treated by drilling small holes (3 to 5 mm) through the hoof rather than by resection of large portions of hoof wall and sole (see Figure 129-1). Two or more holes may need to be placed in the hoof wall or sole to provide adequate drainage and to flush the site. Drilling small holes does not reduce hoof wall strength compared with paring or removing large portions using conventional methods.

Sidebone

Mineralization of the cartilages of the foot (sidebone) is a common radiological finding in draft horses, particularly

in the forelimbs, but is an infrequent cause of lameness. Of 113 draft horses with sidebones, 80 had the condition bilaterally in the forelimbs, and 28 horses had it bilaterally in the hindlimbs. Five horses had unilateral involvement. Draft horses with angular limb deformities are more likely to develop sidebone than are horses with normal bone structure. Sidebone is more common in draft horses with poor hoof quality than in horses with normal hooves. Trauma to the heel and quarters and reduced palmar support are contributing factors. If sidebone is the cause of lameness, lameness grade is usually mild (1 to 2 of 5). Lameness is most common in horses 4 to 7 years of age. Sidebone fractures, occurring in older horses, can cause acute lameness. Lameness is usually most apparent when the horse is working on pavement or other hard surfaces. On soft surfaces the hoof can tip or angle, whereas on hard surfaces the bony column cannot move. Lameness is most obvious when horses are working in circles or tight turns.

Lameness associated with sidebone can be difficult to confirm. Palmar or plantar digital nerve blocks usually greatly improve clinical signs, and palmar nerve blocks at the base of the PSBs abolish lameness. Both nerve blocks provide analgesia to numerous other structures that are more frequent causes of lameness, however. Physical examination is more helpful than is diagnostic analgesia. Tapping on the upper one fourth of the hoof wall (while avoiding hitting the coronary band) with hoof testers or a hammer may elicit pain. A lateral or medial wedge test often causes lameness (see Chapter 8). Thermography is valuable in some horses, showing increased temperature in the area of the sidebone. Radiography is of limited value, because the mere presence of mineralization is not conclusive evidence for lameness diagnosis. Nuclear scintigraphy and magnetic resonance imaging have the potential to help to obtain a definitive diagnosis.

Treatment includes rest and hoof care. The hoof should be trimmed level. Hoof strike should be evaluated dynamically (how it strikes the ground during movement) rather than by just viewing the hoof in a static position. Vertical and parallel grooving may allow the hoof wall to expand and may reduce pressure, but I have not found grooving highly rewarding. The horse should have stall rest or small paddock confinement for 4 to 8 weeks and NSAID therapy. The foot must be balanced properly before the horse resumes a normal exercise program. Fractures associated with large sidebones may be accompanied by OA of the DIP joint. Rarely the PIP joint is involved. Surgical management of draft horses with sidebone fractures often is unrewarding, and I do not recommend it unless conservative management efforts have failed. Conservative management includes an extended period of stall rest (8 to 12 weeks) and then small, level paddock exercise for 6 to 8 months. Healing as shown on radiographs may require extensive time, and even then the fracture still may be evident, surrounded by proliferative exostosis. Unilateral palmar digital neurectomy also can be performed. This will provide relief in most horses unless there is concurrent OA of the DIP or PIP joints.

Quittor

Quittor is defined as a chronic infectious condition associated with one of the cartilages of the foot. A mixed bacterial infection causing chronic or recurrent drainage at or

Fig. 125-3 • Draft horse foot showing chronic scar and granulation tissue associated with quittor.

near the coronary band is most common (Figure 125-3). Trauma is the most common cause of the condition referred to as *necrosis of the cartilage*. Wire cuts and wounds incurred from large calks on the shoes when horses are working in harness or being transported are common histories. Quittor is considerably less common today than it once was.

Surgical management is the only option, because scar tissue and limited circulation preclude successful conservative management with local or systemic antibiotics. Excision of necrotic cartilage and scar tissue is best. Samples should be submitted for aerobic and anaerobic bacterial culture and susceptibility testing. Standing surgery can be performed, but I prefer to use general anesthesia, which reduces the chance of the DIP joint being penetrated, improves the ability to provide hemostasis, and provides maximal restraint during surgery. A tourniquet at the level of the fetlock joint provides excellent surgical hemostasis, and as a precaution I always administer prophylactic broad-spectrum antibiotics before surgery. The DIP joint occasionally is opened, and although penetration does not necessarily indicate surgical failure, an open joint alters the postoperative management protocol. If necrotic material (cartilage or scar tissue) extends distal to the coronary band, adequate distal drainage and flushing require drilling a hole in the hoof wall.¹

Osteitis of the Distal Phalanx

Many draft horses have flat soles and bear substantial weight on the sole and thus are prone to sole bruising and osteitis of the distal phalanx. The condition is most prevalent in the forelimbs and often is associated with improper shoeing or lack of proper hoof care. Draft horses with osteitis of the distal phalanx may assume a stance similar to that seen with traumatic laminitis. Hoof tester examination may be helpful to differentiate these conditions. A laminitic horse is most sensitive immediately dorsal to the apex of the frog in line with the dorsal third of the toe. With osteitis of the distal phalanx, hoof tester pain response usually is less severe and more likely involves the sole in

Fig. 125-4 • Draft horse foot showing the typical appearance of thrush complicated by canker beneath the superficial layer of the frog.

general. Soles may be pink or red, showing indications of bruising, and lameness is worse on hard surfaces or gravel. Mildly affected horses warm out of the lameness, but in horses with severe pain, lameness increases as exercise continues. Radiographs can be difficult to interpret, and a definitive diagnosis is best reached using nuclear scintigraphy, observing increased radiopharmaceutical uptake in the distal phalanx. Management includes the judicious administration of NSAIDs and corrective shoeing. The sole should be protected and minimally pared. Pads frequently are used initially but may be counterproductive in the long run, because the sole has a tendency to become soft and lose thickness. Pads are needed for the first few shoe changes but then should be removed, and the sole should be hardened. To harden the sole, a common mixture referred to as *sole paint* (composed of equal parts of 7% iodine, buffered formalin, and liquid phenol) is applied. This solution is applied to the sole once each day for 3 to 5 days or until the sole becomes hard. Overzealous application can cause the sole to become too hard. Paddock rest for 45 to 60 days is given. If shorter rest periods are given, recurrence is common. Hard, frozen, or rough surfaces should be avoided.

Canker

Canker is not common but is a difficult problem to solve. Canker is proliferative pododermatitis of the frog that may extend to undermine the sole and heel bulbs. The condition can occur in one or all feet and has no predilection for forelimbs or hindlimbs. Often horses are thought to have nonresponsive thrush, but later when the problem persists, canker is diagnosed (Figure 125-4). Canker is seen more commonly in draft horses than in light horses, a fact that may reflect differences in hoof care and environment or simply may represent a breed predisposition. Two clinical signs that differentiate canker from thrush are a foul odor (necrotic) and the presence of granulation-like tissue that bleeds easily when manipulated (Figure 125-5). Lameness is highly variable depending on the severity and

Fig. 125-5 • Chronic canker with proliferative granulation tissue. Infected granulation tissue has undermined the sole and heel.

number of feet involved. Once the superficial layer of tissue is removed, bleeding is often profuse. Creamy exudate is typical initially, especially if the owner has initiated treatment with caustic preparations.

Successful treatment of canker requires patience on the part of the owner and the veterinarian because recurrence is common. The application of a hospital plate shoe is critical, because this shoe allows for long-term treatment and protects the sole. It is important to note that pressure on the sole appears beneficial to healing, similar to that seen with granulation tissue at any site. Hospital plate shoes reduce the cost associated with daily care and management of a bandage. The shoe allows the horse to be exercised. The hospital plate shoe is made and fitted to the foot, and then the foot is blocked. A tourniquet is placed at the level of the fetlock joint, because bleeding during debridement is often profuse. Complete debridement of all abnormal proliferative tissue is often not possible and in fact may be counterproductive, because aggressive debridement may expose uninvolved deep tissue. Dry gauze sponges are packed to apply pressure on the frog and sole when the plate is replaced. Metronidazole appears to be the best topical agent, but I have used tetracycline and sulfapyridine powder successfully. The dressing should be changed daily for the first 10 to 14 days and then as needed. Debridement often needs to be repeated several times. Long-term treatment is necessary, and the owner needs to be prepared to provide it. Caustic compounds are not effective and in fact may worsen the condition. In the final stages of healing, when cornification of the frog is complete, caustic agents may be applied. Sole paint is applied to the sole for 8 to 10 days before the hospital plate shoe is removed. Horses are administered trimethoprim-sulfamethoxazole (15 mg/kg) for 3 weeks starting the day before initial debridement. Penicillin (20,000 IU/kg IM) is also effective, but oral antimicrobial agents are administered more easily.

Osteoarthritis of the Proximal and Distal Interphalangeal Joints, Ringbone

OA of the PIP or DIP joint was diagnosed in 26 draft horses in my series.

Ringbone has been described classically as being periarticular or articular in nature. The prognosis for draft horses with articular ringbone is worse than for those with the periarticular form. Pulling horses (heavy loads) are affected most commonly, especially in the hindlimbs. OA of the PIP and DIP joints appears to occur with similar frequency, because in 26 horses, 11 had PIP, 10 had DIP, and 5 had PIP and DIP joint involvement. Horses with OA of the PIP joint remained serviceably sound for 2.6 years, whereas horses with OA of the DIP joint or of both joints were serviceably sound for only 11 months. Early diagnosis appears to be an important criterion for an improved prognosis, and reducing workload, instituting corrective shoeing, and providing medical management can make a substantial difference in delaying the progression of OA.

Draft horses with short, upright pasterns are predisposed to OA of the PIP and DIP joints, and other factors such as angular limb deformities, toed-in or toed-out conformation, hoof imbalance, and trauma may play a substantial role. Horses required to work on pavement are predisposed to OA of the PIP and DIP joints. Proliferative periarticular changes often result from lacerations or wire cuts. Horses with moderate-to-severe lameness have obvious enlargement of the pastern or coronary band area and heat. The degree of lameness varies from grade 1 to 5, and it worsens with lower limb flexion or after rotation of the digit. Rotation causes a substantial positive response if collateral ligaments are involved in horses with the periarticular form. In horses with OA of the DIP joint, palmar digital nerve blocks generally result in substantial improvement in lameness score. Thorough examination of the foot must be done to eliminate other potential causes of lameness. If the diagnosis is unclear after radiological examination, intraarticular analgesia should be performed. In horses with OA of the PIP joint, palmar digital nerve blocks may provide some improvement in lameness score, but palmar nerve blocks at the level of the PSBs are needed to improve lameness substantially. Intraarticular analgesia can also be used.

Management depends on when the diagnosis is first made. Draft horses with OA and mild lameness should be given rest in a small level paddock for 4 months. I do not use stall rest unless horses are very active, because I have had greater success allowing the horse to walk in a confined area. Hoof imbalance should be corrected, and the horse should be shod with flat shoes without calks, toe grabs, or borium. I recommend oral glucosamine or chondroitin sulfate supplementation or intramuscular injection of a polysulfated glycosaminoglycan (PSGAG). I also inject the joints with a corticosteroid and hyaluronan. Initial and follow-up radiographic examinations are recommended. If the horse is sound and radiological changes do not progress, the horse is put back into a light exercise program, whereas if radiological changes worsen, additional rest and injections are given. Many horses with OA perform for extended periods of time without recurrence of lameness. Horses with severe OA of the PIP or DIP joints have an unfavorable prognosis for athletic use. Medical management is of little benefit, and although spontaneous fusion of the PIP joint may occur, giving an accurate time estimate of when this may occur is difficult. Spontaneous fusion of the DIP joint seldom occurs. Surgical arthrodesis of the PIP joint can be performed by using bone plates or the

three-screw technique with 5.5-mm bone screws (see Chapter 35). A half-limb cast is placed for at least 4 to 6 weeks after surgery. In draft horses the surgical procedure is more difficult than in light horses because the joints are large, removing articular cartilage is difficult, and horses may have difficulty with recovery from general anesthesia. Draft horses in general do not recover well from extended periods (>2 hours) of general anesthesia. The surgical procedure can be long, in particular if there is substantial periarticular new bone formation and fibrosis. Implants can break because of the large size of a draft horse. Because of this, I have used an alternative technique of drilling across the joint with a 4.5- or 5.5-mm drill bit and then applying a half-limb cast without using implants. In horses with substantial periarticular bone proliferation or fibrosis, this technique is my method of choice. Intraoperative radiographs are mandatory to ensure proper placement of the drill bit within the joint. I drill at three to five sites in a fan-shaped pattern from each side of the joint to destroy as much articular cartilage as possible. Breaking a drill bit in the joint is possible, and if this happens, removing the bit generally is not worth the extra time required. The palmar digital artery, vein, and nerve must be avoided during this procedure. A half-limb cast encompassing the foot is applied and maintained for 12 to 16 weeks. Advantages of this technique over those involving implants are that this technique is faster, requires shorter anesthesia periods, and requires no major skin incisions, and implant failure is not a concern. Pain control must be used to maintain reasonable comfort to avoid contralateral laminitis, which is always a concern.

Metacarpophalangeal (Fetlock) Joint Lameness

Problems associated with the fetlock joint are less frequent in draft horses than in other breeds, and most result from direct trauma. Fetlock joint problems plague horses that perform at speed, and therefore draft horses seldom have lameness in this region. Sesamoiditis does occur in draft horses and usually results from suspensory desmitis and insertional injury at the level of the PSB. Sesamoiditis is more common in the hindlimbs than in the forelimbs. An unusual problem of the fetlock joint in young draft horses is osteochondritis dissecans (OCD).

Splints

Exostoses of the second and fourth metacarpal or metatarsal bones (splints) most commonly affect the second metacarpal bone, as in light horses. In 84 draft horses diagnosed with splints, 71 horses had forelimb involvement. Lameness associated with true splint (tearing of the interosseous ligament) is not common in draft horses. Lameness caused by splints is most prominent in the first 2 to 3 weeks after the condition is first recognized and usually resolves with 6 to 8 weeks of rest. Because draft horses do not perform at speed or change direction quickly, splints do not cause long-term lameness. Splints can result from interference injury from the contralateral limb, a problem that usually is corrected by proper shoeing and trimming. Local infiltration of local anesthetic solution in the region of the splint may be performed if the diagnosis is in question. Although a splint may be painful during palpation, missing a problem in the more distal aspect of a limb is easy; therefore diagnostic analgesia should be performed distal to the splint

before local infiltration. Radiographs should be obtained to check for a fracture.

To manage a draft horse with lameness resulting from a splint, I administer NSAIDs for 5 to 7 days and recommend stall rest. If the condition is acute, I use cold water therapy or ice boots for 20 to 30 minutes twice daily and apply support wraps. The horse should be handwalked for 10 minutes twice daily. In horses with chronic splints, I recommend a sweat (50/50 mixture of glycerin and alcohol) for 7 to 10 days. Paddock exercise can be given for 12 hours each day. A total rest period of 60 to 90 days is usually adequate. I avoid overzealous treatment with topical or internal blisters.

Fractures of the splint bones are rare but usually involve the fourth metatarsal bone (MtIV), and they often occur from kick wounds. These fractures often are comminuted and usually infected, because owners do not seek veterinary attention until 2 to 3 weeks after injury. Severe lameness often is not seen or is short lived, so the owner usually is not concerned until drainage starts. If the tarsometatarsal (TMT) joint is involved and infected, the prognosis for return to original use is unfavorable. Many of these fractures heal if horses are given rest and treated with antibiotics. If the articular surface of the TMT joint is not involved, displacement of fragments is minimal, and if the horse is not an athlete, horses with this injury can be treated conservatively. Standing curettage of a draining tract and removal of sequestra can be accomplished in many horses with use of sedation and local analgesia. A culture and antimicrobial sensitivity testing are performed, and the horse is placed on appropriate antibiotics for 3 to 4 weeks; the outcome is often satisfactory. For economic reasons this method also is chosen by some owners for horses intended for athletic use. However, I believe the problem is best treated surgically in those horses that are expected to be athletes. Surgical removal of the distal fractured segment of the MtIV is recommended occasionally, and horses usually have a good prognosis. If greater than 80% of the total length of the MtIV is removed, I use a screw to stabilize the proximal fragment. I do not like placing a screw into an area of known infection if I can avoid doing so. In horses with substantial displacement or a fracture involving the articular surface, internal fixation to realign the fracture is indicated, if the injury is less than 3 weeks old. Fractures older than 3 weeks old can be difficult to realign because callus formation occurs quickly.

Tendonitis and Suspensory Desmitis

Digital flexor tendonitis and suspensory desmitis are not as common in the draft horse as one might expect. Of 45 horses examined for these soft tissue problems, the distribution of these combined soft tissue injuries between the forelimbs and hindlimbs was similar, in contrast to most sports horses. Suspensory desmitis is more common in hindlimbs and often is seen with sesamoiditis. Tendonitis and suspensory desmitis are more common in draft horses that pull heavy loads or weighted sleds. Clinical signs include heat, pain, swelling, and lameness, and diagnosis is usually straightforward. Horses with hindlimb proximal suspensory desmitis may have more subtle clinical signs, and diagnostic analgesia is usually necessary. In horses with early forelimb superficial digital flexor tendonitis, the anastomosing branch of the palmar nerves may be enlarged and

sensitive to palpation before the tendon itself shows clinical abnormalities. Ultrasonographic examination should be performed.

Management of draft horses with tendonitis and suspensory desmitis is similar to that in light horses. Ultrasonographic examination, rest, and a staged return to work are important. I am an advocate of percutaneous tendon or suspensory ligament splitting under ultrasonographic guidance in draft horses. The surgery can be accomplished in a standing horse, using local analgesia and sedation, thus avoiding the need for general anesthesia. Prognosis is guarded to favorable in draft horses with forelimb tendonitis and suspensory desmitis. Draft horses with hindlimb injury, however, have a guarded to unfavorable prognosis, especially if horses are used for pulling heavy loads. Broodmares with chronic, severe suspensory desmitis must be given special attention during late pregnancy because of weight gain. These mares should be housed on level surfaces and alone. Situations that require the mare to move quickly to avoid an aggressive pasture mate or cause the mare to slip while going over rough terrain should be avoided. Muddy or slick footing also should be avoided. Stall rest, although advantageous for healing of the suspensory ligament, is avoided, because these broodmares usually develop substantial ventral edema.

Other Forelimb Lameness

Other causes of forelimb lameness are unusual. Upper limb lameness usually is caused by direct trauma and is not the result of athletic use. Carpal, elbow, or shoulder joint lameness is not common. I have examined only 13 draft horses with carpal lameness. Various manifestations of osteochondrosis are seen in the elbow and shoulder joints.

Sweeny, a neuromuscular disorder thought to be associated with injury of the suprascapular nerve, does occur with some frequency in draft horses. Muscle atrophy may not be obvious for weeks to months, depending on the extent of the injury. Sweeny may result from acute direct trauma, but in draft horses insidious trauma from a collar is the most common cause. This is especially true of poorly fitting collars, or old and worn collars in which the padding is no longer adequate. Collars of inadequate size often are used on today's large-sized draft horses. Some draft horses with Sweeny continue to perform adequately despite muscle atrophy. Diagnosis is made by observing muscle atrophy over the scapula, especially affecting the supraspinatus muscle. Lameness is most likely functional and not related to pain, because horses cannot extend the shoulder joint normally. In some horses, however, the shoulder joint actually may subluxate when the horse is walking or especially turning in a circle. Subluxation results more frequently from external trauma from being kicked or from running into a solid object rather than from collar injury and may involve additional nerve injury.

Management of horses with acute trauma of the shoulder area includes the administration of NSAIDs, corticosteroids, and dimethyl sulfoxide and performance of physical therapy. A water hose with a hard stream of water can be useful for physical therapy. Liniments, massage, handheld muscle stimulators, and heating pads can be useful physical therapeutic modalities as well. The administration of dimethyl sulfoxide (0.3 g/kg sid IV for 3 to 5 days) is recommended in the acute phase. Prognosis is difficult to

assess, but if improvement is not seen in the first 6 to 8 weeks after diagnosis, prognosis becomes less favorable. I have not attempted scapular notch resection in draft horses, but knowing the complications associated with the procedure in light horses leads me to hesitate recommending it.

Unusual Signs Consistent with Lameness Caused by Mange Mites

In the United Kingdom a clinically significant incidence of mange occurs in draft breed horses.² Draft horses often are presented for evaluation of presumed lameness because of a stiff, stilted gait and with abnormal stamping of the limbs to the ground. In these horses careful clinical evaluation reveals areas of dermatitis, but this condition can be confused easily with musculoskeletal pain. I have not seen this to be a problem in draft horses in the United States.

Hindlimb Lameness

Hindlimb lameness occurs frequently in draft horses, and the most common cause is lameness associated with the tarsus (hock joint). Draft horses in general have a predisposition to develop tarsitis, and lameness does not seem to be related to use. The custom of lowering the inside wall of the hoof and attempting to turn the hocks, a shoeing change thought to improve the horse's pulling ability, may predispose a draft horse to tarsitis. To my knowledge, however, this has never been proved in a controlled study. Draft horse shoes often have a large calk on the heel of the lateral branch of the shoe, increasing torque and shear stress on the entire limb. Heel calks are especially detrimental in horses that work on hard surfaces, because the calk does not sink into the surface, thus putting even greater stress on the limb. This method of shoeing causes a flaring of the lateral hoof wall and predisposes the hooves to separation and breakdown of laminae. Even if this method of shoeing is abandoned, at least 12 to 18 months are required for the foot to return to normal.

Tarsus

Draft horses with hock lameness show a variety of clinical signs. The perceived problems by the owner also vary considerably. The horse may stop pulling or may rest its butt on the stall wall when in the barn. Breeding stallions may be reluctant to mount a mare, and when mounted, they may be unable to maintain erection. Horses may be reluctant to back up, back up in crooked fashion, and have difficulty going up and down inclines. The horse may take short strides in harness or may have a change in attitude, sometimes biting other horses. Because the prevalence of hock joint lameness is high, carefully considering this region when evaluating a draft horse with hindlimb lameness is always wise.

Diagnosis may be straightforward, based on clinical signs, or may require diagnostic analgesia to pinpoint the problem. Upper limb flexion tests in draft horses appear to be slightly more accurate as an indicator of hock lameness than the same tests are in light horses, but false-negative results do occur. Pulling the medial splint bone with the fingers (Churchill test) with the limb in flexion also may be of value. The horse may show a positive response while standing, or lameness may be exacerbated after this

Fig. 125-6 • Dorsomedial-plantarolateral oblique radiographic image of a hock of a yearling draft horse. The radiograph was deliberately underexposed to highlight the extensive osteochondrosis lesion involving the distal half of the lateral trochlear ridge of the talus.

maneuver is performed. When the horse is trotting, careful attention is given to the vertical movement of the wings of the ilium (hip or pelvic hike), but if the problem is bilateral, a pelvic hike may not be obvious. Stride length may be shortened when the horse is viewed from the side, and when evaluated from behind or in front, horses have a tendency to swing the limb toward the midline and then place the limb laterally as it strikes the ground. Horses may scuff the toes because of the low arc of limb flight. Bony exostosis on the dorsal medial aspect of the hock joint may be obvious or absent.

Tarsocrural effusion, or bog spavin, is observed commonly in draft horses. This clinical observation often does not correlate with the source of pain. Even if osteochondrosis is suspected or confirmed, intraarticular analgesia always should be performed (Figure 125-6). Although present, OCD fragments may not be the major source of pain, and surgical removal of these fragments may not resolve lameness. Often in draft horses with OCD there is severe tarsocrural effusion, which may improve but is unlikely to resolve even after arthroscopic removal of the offending fragments (Editors). Arthroscopic removal of OCD fragments is often less rewarding in adult horses. In draft horses younger than 2 years of age, arthroscopic removal of OCD fragments is more likely to resolve lameness, however. The decision to perform surgery is based on the level of performance, cosmetic considerations related to joint distention, location of the lesion, and, most important, whether lameness resolves with tarsocrural analgesia.

Horses with OCD lesions located more distally on the trochlear ridges of the talus have a more favorable prognosis than those with lesions located on the proximal aspect. Horses with OCD lesions associated with the cranial aspect of the intermediate ridge of the tibia have a favorable prognosis if lesions are removed early before chronic synovitis or capsulitis occurs. With only a limited number of horses from which to draw experience, lesions seemingly occur more frequently on the lateral trochlear ridge of the talus (tibial tarsal bone) than in any other location in a draft horse. OCD lesions associated with the cranial aspect of the intermediate ridge of the tibia are also quite common in draft horses (Editors).

Lameness associated with OA of the centrodistal and TMT joints is common. Intraarticular analgesia is often necessary, although some veterinarians medicate these joints and assess the clinical response to this treatment. I prefer to perform intraarticular analgesia and consider management options once a definitive diagnosis has been made, however. In my opinion, conservative management should be attempted before corticosteroids are used. I block the TMT and the centrodistal joints first with the horse standing squarely on each limb. In draft horses with exostoses on the medial aspect of the tarsus (bone spavin), confidently blocking the centrodistal joint may be difficult. Two-percent mepivacaine hydrochloride (7 to 12 mL) is injected into each joint using a 20- to 22-gauge, 2.5- to 4-cm needle in the standard locations (see Chapter 10). In most draft horses a twitch is adequate for restraint. Radiographs should be obtained, but unfortunately they are unreliable in confirming the diagnosis of OA. In some draft horses with substantial radiological changes, lameness may originate elsewhere, whereas in some horses with minor or equivocal radiological changes, severe lameness from early OA of these joints is diagnosed. Radiological examination helps to select management options and to determine prognosis, however.

Management of a draft horse with OA of the distal hock joints includes physical and medical and surgical options. Correction of any shoeing or trimming problems should be performed before any other treatment. The foot is balanced in a medial-to-lateral direction according to conformation to achieve a level foot strike. My definition of a level foot strike is that the foot lands evenly when contacting the ground during movement. I remove the large calks and trailers that often are placed on the lateral branch of the shoes. If the horse is not going to be worked for a period, I prefer to shoe the horse without any special trim (calks, toe grabs, or inside rims). The dorsal aspect of the shoe is placed at the white line, and the toe is rasped back to the level of the shoe. Squared-toe shoes also can be used. The heels of the shoe should extend far enough behind to support the plantar aspect of the heel completely. In some horses slight heel elevation improves breakover and comfort. If the lateral hoof wall is flared, it must be rasped at each shoeing, and the lateral branch of the shoe gradually must be adjusted to conform properly to a more normal hoof shape. If borium is needed for traction on hard surfaces, it should be placed so that it provides a level surface on the bottom of the shoe. Uneven stress from borium points may cause hoof wall cracks. Usually, using six to 10 spots of borium on the shoe adequately supports the foot and also provides adequate traction.

Medical management may include oral supplementation, intramuscular administration of PSGAGs, and intravenous administration of hyaluronan. NSAIDs are recommended at the time of shoeing changes, but long-term use of NSAIDs is usually not a solution in the management of chronic distal hock joint pain. Chronic administration often results in gastrointestinal ulceration and additional problems such as colic or colitis. Horses with distal hock joint pain can be given 2 to 3 g of phenylbutazone daily. Intraarticular injection with hyaluronan alone has limited value in draft horses with OA of the distal hock joints, and I prefer to use hyaluronan with methylprednisolone acetate. If there are economic restrictions, the corticosteroid is most important and can be injected alone. The dose of these compounds is similar to that used in the light horse and is not based necessarily on body weight. I increase the corticosteroid dose by about 25% using methylprednisolone acetate (100 mg) in each of the centrodistal and the TMT joints. If treating bog spavin, I use methylprednisolone acetate (120 mg) and hyaluronan (40 mg). I seldom if ever use triamcinolone acetonide in draft horses, because of a concern about laminitis induction and the fact that I often am injecting several joints simultaneously.

Cunean tenectomy is used in some horses, especially those that have obvious enlargement on the medial aspect of the hock (Figure 125-7). Cunean tenectomy is accomplished in a standing horse using local analgesia and sedation. Horses often are put back into work once the skin sutures are removed, 12 to 14 days after surgery.

Stifle Joint

Draft horses have long been thought to have more stifle joint lameness than do light horses, but when reviewing the records of 745 draft horse lameness examinations, only 10 horses had primary lameness of the stifle joint. Perhaps long ago, when draft horses were used daily to pull heavy loads, the frequency of stifle lameness may have been far greater than it is today. Of these 10 horses, three had bilateral idiopathic effusion of the femoropatellar joint. One horse had bilateral subchondral bone cysts of the medial femoral condyles, one had upward fixation of the patella, and five had trauma from kick injuries. Poor conformation and extended stall confinement predispose some draft horses to upward fixation of the patella. Emaciated horses or those with substantial weight loss also are predisposed to the condition. I make every attempt to correct upward fixation of the patella by using conservative management including foot care, improving muscle tone or conditioning, and improving nutritional intake. Raising the heel often alleviates the problem, and block wedges to raise the angle of the hind feet 6 to 10 degrees are needed. Heel elevation is reduced gradually as the problem is rectified. Improved muscle tone and exercise are beneficial, as is avoiding prolonged periods of stall confinement. Backing exercise strengthens the quadriceps muscles and is a useful form of physical therapy. Internal blisters, injected at the origin and insertion of the patellar ligaments, may cause mild fibrosis and thus tighten the joint. This treatment is used less frequently now than in the past because the preparations need to be special ordered. I seldom if ever elect medial patellar desmotomy as my initial treatment. If conservative management is unsuccessful, desmotomy needs to be performed. The procedure should be done in

Fig. 125-7 • The dorsal aspect of the left hock of a draft horse showing bony exostosis of the dorsal medial aspect (arrow). If lameness was confirmed to originate from the lower hock joint region, this horse would be a candidate for cunean tenectomy.

the standing horse and not under general anesthesia and should be done with a sharp, strong-backed bistoury. This procedure should not be attempted in a draft horse with an ordinary scalpel handle and blade, because the risk of the blade breaking during the surgery is real. Medial patellar desmoplasty (splitting) would be a suitable alternative to desmotomy in draft horses (see Chapter 48 [Editors]).

Shivers

Shivers is considered a progressive, degenerative neuromuscular disease predominantly affecting draft horses or other large-breed horses (see Chapter 48). Various causes have been suggested, including immune-mediated disease following viral infection or strangles and exposure to organophosphates. Polysaccharide storage myopathy has been put forth as a possible cause, but like previous proposed causes, this one may go by the wayside. Clinical signs include an involuntary jerking or twitching most frequently affecting the hindlimbs and the tail. A reflex-like maximum degree of flexion can be seen. Clinical signs often are noticed first by the farrier, because manually picking up the hindlimb frequently stimulates the jerking movements. Signs may be most obvious when the horse first starts to walk, or is backed up or is turned sharply.

On occasion, twitching of the muzzle, lips, and ears and forelimb involvement occur. The condition may improve with rest but usually returns when the horse is put back into work.

Currently, no effective treatment is available. Shivers has been confused with stringhalt in some horses, and the surgical procedure, lateral digital flexor tenectomy, has been performed erroneously. Muscle biopsy to check for polysaccharide storage myopathy and treatment with high-fat, low-carbohydrate diets may be warranted, but definitive proof that polysaccharide storage myopathy is the cause of shivers may be difficult to substantiate. Horses still can be worked, but often owners elect to use them sparingly.

LAMENESS OF FOALS, WEANLINGS, AND YEARLINGS

Young draft horses require careful monitoring and early attention to lameness conditions. Lameness is often multifactorial and is related to nutrition, genetics, and environment. Early diagnosis and management of lameness appear more critical in draft horse foals than in light horse foals. Often the size and strength of draft horse foals gives the erroneous impression that they can overcome many problems.

Infectious Arthritis

Infectious arthritis is common in draft horse foals and may be related to a high frequency of umbilical problems. Umbilical hernia, umbilical infection, and patent urachus are more common in draft horse foals than in light horses. Careful examination and treatment of the umbilicus at birth is mandatory, and the umbilicus should be monitored closely for a minimum of 3 weeks. Compared with light horse foals, draft horse foals are often slower to stand and nurse after birth, leading to many infectious processes. Owner education is important, not only in assisting slow foals up to nurse but also in careful, daily evaluation of joints. Early and aggressive management of infectious arthritis and umbilical remnant infections should be performed (see Chapters 65 and 128).

Developmental Orthopedic Disease

Draft horses are affected by all of the various manifestations of developmental orthopedic disease (DOD), including flexural deformities, epiphysitis and physitis, osteochondrosis, angular limb deformities, and vertebral malformations (wobbler syndrome). A multifactorial cause is suspected, including nutrition (calcium/phosphorus ratios and trace mineral levels) and hereditary factors (certain bloodlines have a high prevalence). Hereditary factors are complex and include high growth rate, feed deficiency conversion, milk production, and individual horse size.

Physitis and Epiphysitis and Flexural Deformities

Physitis and epiphysitis and flexural deformities are closely related and seldom if ever a single problem. These conditions are seen over a wide age range from 6 weeks to 24 months, but peak occurrence is in foals 4 to 12 months of age. When raising large horses, owners have a tendency to overfeed, resulting in high-energy rations, fast growth, and nutritional stress, all of which include the possibility of

DOD. My experience with some 300 draft horse foals suggests a distinct correlation between the frequency of DOD and nutritional management. Foals having the highest frequency of DOD were fed free-choice high-quality alfalfa hay, approximately 0.015 kg of feed per kilogram of body weight per day of a 16% protein grain ration, and two vitamin-mineral supplements. Foals were fed in groups of six to 10 in 5- to 6-acre paddocks. Group feeding allowed the aggressive eater to consume far more than the prescribed amount of grain, and of course hay was fed free choice. None of the foals was thin or malnourished, but numerous foals were obese. Overweight foals, yearlings, and 2-year-olds do not exercise properly, a fact that exacerbates problems associated with excess ration. Under these conditions, two to four foals per group were affected with DOD each year.

To correct this problem, the nutritional program was revamped. The owner accepted the fact that yearling size would be slightly less than previously attained, but that DOD would occur less frequently. Anecdotally, buyers of yearlings from this group had complained in previous years that 2-year-olds had become lame when training had started. The nutrition was changed as follows. The hay ration was given at a 50/50 mixture of alfalfa to timothy. Hay was fed at a rate of 0.015 kg per kilogram of body weight per day, or the amount the foals could consume in about 16 hours. The grain ration was reduced to approximately 0.01 kg per kilogram of body weight per day of a 14% protein ration. Only one vitamin-mineral supplement was given. Foals were grouped according to size, age, and disposition and were monitored closely and checked every 2 weeks by the farm veterinarian. Changes in conformation (becoming upright in the pastern and fetlock) or enlargement (heat and pain) of the growth plates were noted.

Any foal with a change in the pastern or fetlock angle (developing more upright conformation), joint effusion, or physitis was treated immediately. Stall rest was given for 7 to 10 days, the feed intake was reduced, and the foal subsequently was given controlled exercise in a small paddock. Foals were fed only timothy hay, and the grain ration was reduced to 0.002 kg per kilogram of body weight per day. They were placed on phenylbutazone (2.2 mg/kg bid for 3 consecutive days and then every other day for 3 more days). They were maintained in this environment until the problem resolved. Any hoof imbalance or growth abnormality was treated. A 60% decrease in DOD was noted the first year, and now that farm management has become more attentive to noticing early signs of DOD, the frequency of this complex of diseases is now less than 10%.

Osteochondritis Dissecans and Osteochondrosis

In my experience, osteochondrosis is observed more commonly in draft horse foals than in light horse foals. In draft horse foals the tarsocrural and femoropatellar joints are affected most commonly. Any joint can be affected, including the cervical vertebrae. Horses with osteochondrosis show varying degrees of lameness from 1 to 4 of 5 degrees. Lameness is less frequent with osteochondrosis lesions of the tarsocrural joint than with osteochondrosis of the stifle. Loose OCD fragments in the femoropatellar joint should be removed as soon as possible. Arthroscopic surgery does not guarantee success but improves the prognosis for athletic use. In my experience, draft horses

have a more guarded prognosis for future soundness with osteochondrosis of the stifle than do light horses. I am unsure if this is related simply to the size of the horse or the amount of pulling many of these draft horses are expected to do, but only about 50% of draft horses are sound after surgery. Early diagnosis and surgical

management improve prognosis considerably. In some foals without loose OCD fragments, conservative management has resulted in a favorable outcome. Large OCD defects involving the lateral trochlear ridge of the femur have healed based on radiological examination, but this process may take up to 6 months to occur.

Chapter 126

Lameness in the Pony

Andrew M. McDiarmid

Horses under the height of 14 hands 2 inches (148 cm) at the withers generally are recognized as ponies. Despite this classification, ponies of some breeds are referred to as *horses*: for example, Icelandic (toelter) horses. Many native pony breeds are found throughout the world—for example, Asturian (Spain), Connemara (Ireland), Fell (England), Gerrano (Portugal), Highland (Scotland), M'Bayar (Senegal), Merens (Pyrenees), Ob (Russia), Pindos (Greece), and Welsh ponies. Several small island breeds also exist—for example, Balearic, Eriskay, Faroe Island *horse*, and Chincoteague ponies. The size and conformation of most pony breeds have evolved over centuries because of specific work requirements and geographical isolation. Several breeds are endangered, including the Yonaguni and Noma in Japan and Sorraia in Spain, and some have become extinct—for example, the Fen, Galloway, and Tarpan. Attempts are actively being made to prevent extinction of several breeds—for example, the Kerry bog pony in Ireland and the Taishuh in Japan. In recent times new breeds of pony have evolved, including the Welara and Pony of the Americas. Despite this, most ponies are crossbred.

Ponies have a considerable range of height, weight, and conformation and are involved in most spheres of equine work, including show jumping, eventing, dressage, driving, and general pleasure activities. Many ponies show great athletic ability, and when used for show jumping, they often jump heights similar to their own height at the withers. Ponies have a long life expectancy and can remain in athletic work well into their twenties. Although a small number of ponies are used for high-level competition work such as eventing and show jumping, most are used for general purpose work, when they may be ridden only in the summer months. General purpose ponies tend to be much less valuable than horses and are ridden predominantly by children, which may create emotional and financial conflicts for owners (parents) when deciding the appropriate treatment of a seriously injured pony. Many general purpose ponies remain at grass all year round and do not have access to a stable. Successful competition ponies often change ownership, at high prices, every 2 or 3 years as children outgrow them.

Few reports in the literature describe orthopedic conditions specifically affecting the pony. In this chapter I hope

to give an overview of some of the conditions that are recognized in the pony.

LAMENESS AFFECTING THE PONY

Ponies develop orthopedic problems similar to those in horses, but the overall prevalence of lameness in the pony is less than in the horse. This may be because of differences in temperament and body weight. With a relatively older population the incidence of some specific orthopedic conditions affecting older ponies may appear higher than in horses, but the prevalence is often unclear and may, for some conditions, be similar (e.g., laminitis as a result of Cushing's disease).

LAMENESS EXAMINATION

Gait assessment in ponies can be challenging because they can have a higher limb speed than horses, and the larger, heavier pony breeds (e.g., Highland) often have a base-wide gait behind, which may make assessment of hindlimb lameness difficult. Several breeds also have gaits additional to walk, trot, and canter; these include the South African, Basotho pony, and Icelandic horse. For small ponies the handler may have to walk when leading a trotting pony, rather than run, to keep the limb speed to a rate at which the observer can detect low-grade lameness.

The low height of some ponies compared with most veterinary surgeons may create difficulties with assessment of the lower limb, and excessive force or torsion can easily be applied to the distal joints when a flexion test is performed.

In small ponies, care should be taken not to apply excessive pressure with hoof testers and, if the veterinary surgeon is tall, not to flex or twist the lower limb excessively in an effort to raise the foot to a convenient height to use the testers. Paradoxically, in comparison with horses many ponies have harder hoof horn, making eliciting foot pain difficult, so care always should be taken when assessing the response to hoof testers. The use of small or adjustable hoof testers is advisable for ponies.

Ponies can have a positive response to lower limb flexion tests despite being sound and performing to the owner's expectations.

DIAGNOSTIC ANALGESIA

Some ponies are strong-willed, which can limit a conventional lameness evaluation using perineural or intrasynovial analgesia. Using a nose twitch or a low dose of an α_2 -sedative may aid this (e.g., 40 to 60 mcg of romifidine per kilogram or 0.6 to 0.9 mg of xylazine per kilogram

intravenously). In some ponies the lower limbs may have thick skin and be very hairy, making accurate palpation of the structures difficult, particularly finding the site for a palmar digital nerve block. I am conscious that because of the relatively shorter limbs in ponies, local anesthetic solution may diffuse further than in the horse, and a reduced amount of local anesthetic solution is used for perineural analgesia (e.g., 1 mL of mepivacaine hydrochloride for each nerve for palmar digital or palmar [abaxial sesamoid] analgesia).

IMAGING CONSIDERATIONS

For most clinical situations a similar number of radiographic images are required to examine the lower limb of a pony as for a horse. Although obtaining good-quality radiographs of the lower limb is generally easier, some important lesions may be more subtle than in the horse, particularly those involving the distal interphalangeal (DIP) joint and navicular bone. Conversely, one should note that a substantial amount of joint degeneration can be present in some sound ponies. It is therefore important in the pony to undertake intrasynovial analgesia to confirm that any periarticular and intraarticular abnormalities are associated with joint pain.

In some ponies, particularly those kept at grass, a substantially increased thickness of skin in the distal limbs, pelvis, and thoracolumbar areas can be present and reduces skin penetration by ultrasound waves, resulting in poor ultrasonographic images. I have found that shaving the hair and hosing the area to be scanned with warm water for 15 minutes often substantially improves the quality of the image.

TEN MOST COMMON CONDITIONS AFFECTING COMPETITION PONIES

Competition ponies appear to have a reduced prevalence of lameness in comparison with horses; however, the common conditions they develop mimic those found in competition horses. The following list contains the 10 most common lameness conditions in the ponies treated in my practice:

1. Laminitis and other foot-related injuries
2. Distal hock joint pain, osteoarthritis of the distal tarsal joints (bone spavin)
3. Desmitis of the accessory ligament of the deep digital flexor tendon
4. Conditions of the digital flexor tendon sheath
5. Osteoarthritis of the metacarpophalangeal joint
6. Superficial digital flexor tendonitis
7. Exertional rhabdomyolysis
8. Osteoarthritis of the carpus
9. Osteoarthritis of the femorotibial joint
10. Injuries of the palmar or plantar annular ligament

LIMB DEFORMITIES

Mild angular limb deformities in ponies are common, but few affect performance or require medical or surgical correction. In many native breeds in the United Kingdom a small degree of carpal and fetlock valgus deviation is common. The persistence of a full-length ulna and fibula

has been associated with the development of severe angular limb deformities in Shetland ponies.¹ This may be a form of atavism, the inheritance of a characteristic from remote, rather than recent, ancestors.

Congenital laxity of the digital flexor tendons in the hindlimb of Shetland ponies is not uncommon and can be associated with hyperextension of the DIP joint. Treatment is similar to that in the horse.

Adactyly (absence of all or part of a normal digit) and polydactyly (duplication of all or part of a digit beyond the normal number) and other congenital musculoskeletal defects have been recorded in ponies.²

JOINT DISEASE

Osteochondrosis

Rarely do ponies have lameness associated with osteochondritis dissecans (OCD). Histopathological evidence of osteochondrosis specifically in ponies has been reported only in the lateral trochlear ridge of the femur.³ Based on a limited number of ponies, in my opinion the most commonly affected joints are the tarsocrural and femoropatellar joints, and lesions are found at the same recognized sites as in the horse—namely, the cranial aspect of the intermediate ridge of the tibia, trochlear ridges of the talus, the medial and lateral malleoli of the tibia, and the lateral trochlear ridge of the femur. Osteochondrosis has been seen particularly in ponies bred for showing,⁴ perhaps because these ponies were receiving high feed intakes in an effort to improve show ring appearance.

Lameness associated with a subchondral bone cyst in the medial femoral condyle in the stifle is not uncommon in the pony.

Osteoarthritis

Ponies develop osteoarthritis (OA) in similar joints as horses. However, many ponies have mild-to-moderate joint degeneration, are clinically sound, and perform to the level of the owner's expectation (Figure 126-1). OA in ponies tends to be primary rather than secondary to a previous intraarticular condition, such as intraarticular chip fractures, OCD, osseous cystlike lesions, or ligamentous damage.

Scapulohumeral Joint

Shetland and Miniature Horses have a higher prevalence of OA of the scapulohumeral joint than do other equine breeds.⁵⁻⁷ This typically occurs in young ponies; the mean age in one survey was 5.2 years. The lameness is usually unilateral but can be bilateral and is sudden in onset and severe (grade 4 to 5 of 5) in degree. Lameness is characterized by a reduction in the cranial phase of the stride and a low arc of foot flight. Radiological abnormalities may not be present in the acute stage.⁵ Ultrasonography may be used to assist in the diagnosis.⁸ No reported treatment has resulted in successful resolution of the lameness. Some Shetland ponies have a flatter and more shallow glenoid cavity of the scapula than other equine breeds, and this may be caused by a primary joint dysplasia that could predispose Shetland ponies to OA of the scapulohumeral joint.⁶ In Miniature Horses scapulohumeral joint OA can be associated with an inability of the owner or veterinarian to pick up either forelimb.⁷ Ponies with severe bilateral OA of the scapulohumeral joint may exhibit an unusual,

Fig. 126-1 • Lateromedial radiographic image of the metacarpophalangeal joint of a 12-year-old jumping pony. Periarticular osteophytes on the articular margins of the proximal and distal aspect of the proximal sesamoid bones reflect osteoarthritis. There is also evidence of supracondylar lysis (A) on the palmar aspect of the third metacarpal bone and villonodular (proliferative) synovitis (B) on the dorsal border. This pony had met the owners' expectation until 5 weeks before this examination.

compensatory hindlimb gait deficit in an attempt to redistribute weight to the hindlimbs (Editors).

Carpus

When compared to horses older ponies appear to have an increased incidence of OA of the carpometacarpal joint, often referred to as *carpal spavin*. The radiological abnormalities found within the carpometacarpal joint are similar to those of OA of the distal tarsal joints, and periosteal new bone and enthesophyte formation on the abaxial margins of the second and fourth metacarpal bones may also be present.⁹

I have observed several lame ponies with restricted flexion of the carpus and radiological evidence of carpal joint degeneration, but the lameness was abolished by perineural or intrasynovial analgesia in the more distal aspect of the limb. Restricted carpal flexion without overt lameness may result in a pony being presented because of a history of tripping and concern for the safety of a child rider.

Stifle

In a retrospective study of stifle lameness, a higher incidence of OA of the femorotibial joints was noted in Highland ponies compared with the normal referral horse population at the University of Edinburgh.¹⁰ The ponies have sudden-onset, severe (grade 4 to 5 out of 5) lameness associated with damage to the menisci and collateral or cruciate ligaments. Ultrasonography and arthroscopy are useful to assess the extent of the soft tissue damage. In some of these ponies concurrent abnormalities in the articular surface of the medial femoral condyle, as described in horses, were present.¹¹ The extent of the meniscal and ligament damage was such that treatment was generally unsuccessful. OA

of the femoropatellar joint can occur in Shetland Ponies and Miniature Horses secondary to chronic lateral luxation of the patella¹² (see following discussion).

Hock

OA of the distal tarsal joints (bone spavin) is a common cause of hindlimb lameness in ponies, but as in other joints, intrasynovial or perineural analgesia is advisable to confirm the relevance of any radiological changes. Icelandic horses appear to be predisposed to OA of the distal hock joints.¹³ An epidemiological study showed that 23% of Icelandic horses in Sweden had radiological signs of bone spavin.¹⁴ A causal relationship has been found between hindlimb lameness and radiological evidence of bone spavin and the Icelandic horses' ages and hock angles. No relationship was found with environmental factors such as training and showing.¹⁵ The lameness found in Icelandic horses is often mild, despite moderate-to-severe radiological changes.¹³ OA of the talocalcaneal joint has been seen in ponies,¹⁶ and in my opinion the incidence is higher in ponies than horses. Surgical arthrodesis is the preferred treatment for functional soundness, but the prognosis is guarded.¹⁶

Other Specific Joint Conditions

Luxation of the Coxofemoral Joint

Rupture of the coxofemoral ligaments and secondary luxation of the coxofemoral (hip) joint have a higher prevalence in the pony than in the horse (Figure 126-2).¹⁷ This may be because in horses, unlike in ponies, the ilium tends to fracture before luxation of the hip occurs,¹⁸ although marginal fractures of the acetabulum have been seen with luxation.¹⁹ In the pony, ligament rupture usually occurs after trauma, and the head of the femur is often displaced in a craniodorsal direction. Affected ponies adopt a characteristic posture with outward rotation of the foot and stifle, inward rotation of the tarsus, and a pronounced shortening of the affected limb. Open or closed reduction has been used to treat the luxation, but the prognosis for long-term soundness is poor.¹⁷ Successful closed reduction has been noted in two ponies that were seen within 12 hours of the initial injury.¹⁹ Successful surgical management of a Miniature Horse with coxofemoral luxation using open reduction and a novel toggle suture, synthetic capsulorrhaphy, and trochanteric transposition has been reported.²⁰ Ponies with unsuccessful reduction or irreducible luxation can be salvaged for breeding or companion purposes by excision arthroplasty.²¹ Coxofemoral luxation is often complicated by upward fixation of the patella.^{18,21} Ligament rupture may occur without luxation of the coxofemoral joint, and the clinical signs are similar to those of luxation except for the absence of limb shortening.¹⁸

Dysplasia of the Coxofemoral Joint

Hip dysplasia has been reported in the Norwegian Dole and a Shetland pony colt.²² In the latter, hip dysplasia was associated with the development of OA in the coxofemoral joint.

Luxation of the Patella

Lateral (sub)luxation of the patella in Shetland ponies is common.²³ The condition is usually congenital but can be

Fig. 126-2 • A, Typical appearance of luxation of the coxofemoral joint in a pony. Note the outward rotation of the stifle and foot, inward rotation of the tarsus, and shortening of the right hindlimb. **B**, Ventrodorsal radiographic image of the right coxofemoral joint demonstrating the caudodorsal luxation of the head of the femur.

acquired and affects one or both hindlimbs. A distinction should be made between (sub)luxation and congenital permanent lateral luxation (see the following discussion). The cause of the condition is thought to be malformation of the trochlear ridges and groove, but rupture of the medial femoropatellar ligament has been reported in one pony.²⁴ Postmortem examination usually reveals that (sub)luxation is associated with a broadening and flattening of the medial and lateral trochlear ridges of the femur, particularly the distal aspect of the medial trochlear ridge. Whether these changes are congenital or are caused by bone modeling is unknown. The clinical signs vary, but in most ponies the patella can be easily manipulated laterally and then replaced in the trochlear groove, and in some ponies the (sub)luxation can be observed during motion. The degree of (sub)luxation varies among ponies and can vary during an individual pony's life. Patellar luxation can be observed in lateromedial and caudocranial radiographic images, but to confirm (sub)luxation a cranioproximal-craniodistal oblique (skyline) image of the patella is required. In ponies with (sub)luxation the patella may appear an abnormal shape on the skyline projection, but this is caused by

rotation and abnormal positioning and not by bone modeling.²³ Ponies with lateral luxation of the patella have been treated successfully by medial imbrication and lateral release incision¹² or imbrication and recession sulcoplasty.²⁴ Hermans and colleagues,²³ using a limited breeding experiment with a group of Shetland ponies, found evidence to suggest monogenic autosomal recessive hereditary transmission of this defect.

Congenital permanent lateral luxation of the patella is also seen in Shetland ponies. Affected newborn foals are unable to extend the stifle fully and therefore have a crouched, squatting position when standing. The lateral trochlear ridge of the femur in affected foals is often flat rather than convex.²³ The prognosis for successful treatment is poor.

Upward Fixation of the Patella

Intermittent upward fixation of the patella is a not uncommon condition in ponies, affecting young ponies (typically 2 to 3 years old), and older ponies secondary to an orthopedic problem in the limb. The clinical presentation is similar to that in the horse.

Hemarthrosis

A higher incidence of hemarthrosis has been noted in ponies than in horses,²⁵ and this is often secondary to a systemic disease such as a blood clotting disorder or hepatopathy. Affected ponies have acute-onset lameness with a severely painful joint effusion(s).

Subluxation of the Proximal Interphalangeal Joint

Nontraumatic dorsal subluxation of the proximal interphalangeal (PIP) (pastern) joint has been recorded in the hindlimbs of ponies.²⁶ The condition usually occurs bilaterally in young ponies (Figure 126-3). Dorsal subluxation of the PIP joint is observed when the affected limb is not bearing weight. The subluxation is reduced as weight is borne on the affected limb, and an audible clunk often accompanies joint reduction. Tenotomy of the medial head of the deep digital flexor tendon (DDFT) in the proximal metatarsal region has produced good results in treating this condition.²⁶ Unilateral dorsal subluxation of the PIP joint has been observed in a 3-year-old pony secondary to infectious arthritis of the tarsocrural joint.²⁷ The subluxation resolved after successful treatment of the infectious arthritis.

Treatment of Joint Disease

Nonsteroidal antiinflammatory drugs should be used with care in lightweight ponies because they may be more susceptible to phenylbutazone toxicity.²⁸ (Recommendations

by some phenylbutazone-supplying drug companies in the United Kingdom state that the maximum level of phenylbutazone in ponies is 4.4 mg/kg orally on alternate days compared with a maximum level of 4.4 mg/kg twice daily for horses.) The ulcerogenic properties of orally administered phenylbutazone are possibly more pronounced in ponies because of less efficient gut absorption. Systemic and intraarticular corticosteroid use in ponies also has to be undertaken with caution because of the potential for development of laminitis.²⁹

If arthroscopy or arthrotomy is undertaken in the diagnosis or treatment of joint disease, one should note before giving a prognosis that ponies appear to accommodate greater cartilage degeneration than horses.

A Fell pony foal with infectious arthritis should be checked for immunodeficiency syndrome before treatment is initiated.³⁰

FRACTURES

Common fractures seen in horses (i.e., proximal phalangeal fractures, third carpal bone slab fractures, and condylar fractures of the third metacarpal or the third metatarsal bones) are rare in ponies. Most fractures are secondary to trauma. Hindlimb fractures, particularly involving the lateral splint bone (fourth metatarsal bone [MtIV]), often result from kicks from other horses.

In some ponies, closed fracture reduction and using a cast alone may result in successful bony union in fractures that would require internal fixation in a horse. The lighter weight of most ponies also means that the use of internal or external fixation of long bone fractures is more successful than in a horse. Repair of complete fractures of the humerus, tibia, and radius that would require euthanasia in a horse can be attempted in lightweight ponies (<300 kg).³¹ Treatment may involve using intramedullary implants such as a single Steinmann pin, stacked pin fixation, or intramedullary interlocking nails. External fixation for comminuted lower limb fractures (e.g., proximal phalanx) is also more successful in the pony.³² External fixation using a transfixation cast, with or without a U-bar,³³ or an equine modified type II external skeletal device may be successful.³⁴

Many fractures of the splint bones (second and fourth metacarpal bones, and the MtIV), including proximal fractures, heal satisfactorily with conservative management in the pony. I also have found in the pony that complete excision of the MtIV as previously described³⁵ is successful in treating fractures of the proximal third of the MtIV; however, this occasionally leads to instability of the tarsus.

In ponies with severe or multiple fractures of the carpus, pancarpal or partial carpal arthrodesis can also be considered.³⁶ Arthrodesis of the scapulohumeral joint of a Miniature Horse also has been described.³⁷

It may be important when undertaking internal (or external) fixation in older ponies to assess whether the pony may be compromised systemically by Cushing's disease, because this potentially could result in delayed fracture healing and problems with implant failure.

Stress fractures in ponies are rare but have been recorded.³⁸

Fig. 126-3 • Bilateral nontraumatic dorsal subluxation of the proximal interphalangeal joints in a 3-year-old Welsh pony. The condition resolved after tenotomy of the medial head of the deep digital flexor tendon.

FOOT-RELATED PROBLEMS

Ponies generally tend to have better foot conformation than do horses, and the prevalence of long-toe, low-heel foot conformation appears to be lower than in the Thoroughbred. Navicular disease does occur in ponies, but the incidence is considerably lower than in the horse.³⁹ Intrasyovial analgesia of the DIP joint or navicular bursa should be undertaken to confirm any suspected radiological changes in the flexor surface of the navicular bone. Lesions within the DDFT and collateral ligaments of the DIP joint have been detected in ponies with the use of magnetic resonance imaging. The incidence of collateral desmitis of the DIP joint and DDFT injuries in competition ponies appears similar to that found in competition horses.⁴⁰

Some degree of ossification of the cartilages of the foot (sidebone) is a common radiological finding in ponies,⁴¹ especially in native pony breeds. As in horses, this is rarely associated with lameness.

LAMINITIS

The incidence of laminitis in ponies is high, and this may be the result of an innate insulin insensitivity.⁴² Many of the affected ponies are obese, and a considerable amount of research has recently been carried out comparing human peripheral vascular disease and equine laminitis.⁴³ The term *equine metabolic syndrome* has been introduced to describe laminitis in obese mature ponies.⁴⁴ It has been proposed that hyperglycemia results from insulin insensitivity and causes impaired endothelial function and increased vascular tone. This may involve decreased nitric oxide production, increased release of endothelin-1, increased expression of matrix metalloproteinases, increased lipid oxidation, and increased vasoconstrictor eicosanoids. Dexamethasone suppression tests or adrenocorticotrophic hormone (ACTH) stimulation tests give results within normal reference ranges for these ponies, ruling out underlying pars intermedia dysfunction.⁴⁴ It is now common to screen for insulin insensitivity in ponies using a variety of factors.⁴³ Exercise appears to improve insulin sensitivity in ponies.⁴⁵

In the United Kingdom many ponies used for showing are obese and have a high incidence of equine metabolic syndrome. These ponies often have repetitive annual bouts of laminitis, particularly in the spring, and many respond quickly to acute therapy within a matter of days. Metformin (dimethylbiguanide) at a dose of 15 mg/kg bid orally has recently been shown to improve insulin sensitivity and is rapidly gaining considerable support in the United Kingdom for the treatment of equine metabolic syndrome.⁴³ Chromium has also been used to improve insulin sensitivity in ponies.⁴⁶ Trilostane, a 3-hydroxysteroid dehydrogenase inhibitor that acts to inhibit adrenal steroidogenesis, was found in one study to reduce the quantity of phenylbutazone therapy required in the treatment of horses with severe laminitis as a result of Cushing's disease.⁴⁷ It has also been used to assist conventional therapies for ponies with laminitis.⁴⁴

If ponies with chronic laminitis do not receive corrective farriery, then many secondary complications can occur in the subsequent months, including recurrent

Fig. 126-4 • Foot of a pony with chronic laminitis that has not received any corrective farriery. Note the extremely long toe and laminitic rings.

subsolar hemorrhage, onychomycosis-induced white line disease,⁴⁸ and abscess formation within the dorsal wall (Figure 126-4). Dorsal wall resection is indicated in treating some ponies with laminitis, and this can reduce the incidence of chronic problems.⁴⁹ Repetitive bouts of laminitis also can lead to hoof and distal phalangeal deformation, resulting in the need for the construction of modified shoes for each foot.⁵⁰ The deformation also can result in substantial gait alterations.

In a survey of horses and ponies with laminitis, the prognosis for horses was found to be no different than that for ponies.⁵¹ Restricted access to grass may need to be enforced to prevent laminitis in general purpose ponies that are never stabled. This can involve mowing the field, strip grazing, or muzzling the pony for part of the day. Care should be taken, however, not to undernourish ponies to prevent laminitis because of the potential development of hyperlipemia.⁵²

The incidence of Cushing's disease is higher in ponies than in horses,⁵³ and the diagnosis of Cushing's disease should always be considered in an older pony with laminitis.

SOFT TISSUE INJURIES

Superficial Digital Flexor Tendonitis

Superficial digital flexor (SDF) tendonitis has a lower incidence in ponies than in horses. Tendonitis does occur in older ponies⁵⁴; however, it is often associated with desmitis of the accessory ligament of the DDFT (ALDDFT).⁵⁵ Tendonitis may not necessarily occur after strenuous exercise, and the site of the superficial digital flexor tendon (SDFT) damage can be in the proximal metacarpal region or within the carpal canal.⁵⁶

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT (inferior or distal check ligament), in both the forelimbs and hindlimbs, has a higher incidence in ponies than in horses.⁵⁷⁻⁵⁹ In an in vitro study the forelimb ALDDFT ruptured at lower forces in older horses and ponies, which suggested that an age-related degeneration occurs within the ligament.⁶⁰ Because of the relatively older pony population, the prevalence of ALDDFT desmitis therefore may be similar to that in the horse. Clinically in

the forelimb, desmopathy causes an acute-onset lameness and swelling in the proximal, palmar aspect of the metacarpal region. In the hindlimb a similar situation occurs, but desmopathy can also develop as either an insidious or a sudden onset of postural changes.⁵⁹ Ultrasonography may show a focal area of reduced echogenicity or disruption of the entire cross-sectional area of the ligament. The damage may occur for part or the entire length of the ALDDFT. Prompt aggressive antiinflammatory therapy is required in the acute stage to prevent adhesion formation linking the ALDDFT to the SDFT around the parietal layer of the carpal (or tarsal) sheath.^{58,59} Treatment recommended for ponies with desmitis of the ALDDFT is similar to that recommended for SDF tendonitis in the horse.⁶¹ If extensive adhesion formation occurs in the forelimb, an acquired flexural deformity of the metacarpophalangeal joint may develop, which is difficult to treat.⁵⁸ Ponies with hindlimb ALDDFT desmitis and postural changes have a very poor prognosis for a return to full soundness.⁵⁹ I have used extracorporeal shock wave therapy in a limited number of ponies with excessive adhesion formation associated with forelimb ALDDFT desmitis. After treatment, the adhesions reduced extensively in size, but I am unsure if this altered the long-term prognosis.

Digital Flexor Tendon Sheath

Tendonitis of the DDFT within the digital flexor tendon sheath (DFTS) is not an uncommon injury in ponies,^{62,63} but primary DDF tendonitis further proximally in the metacarpal or metatarsal region is rare. It is my opinion that DDFT injuries within the DFTS are more common in the heavier cob types than in lighter ponies. Ponies with tendonitis have an acute-onset lameness with a painful DFTS effusion.⁶³ There are two forms of injury: a focal tear within the central core area of the DDFT⁶² and a marginal longitudinal tear.⁶³ Focal lesions within the core of the tendon can be detected by ultrasonography as areas of reduced echogenicity, occasionally with areas of dystrophic mineralization.⁶⁴ The associated lameness is abolished by intrasynovial analgesia of the DFTS. The lameness is often slow to resolve (8 to 12 months), treatment is prolonged (often 15 months), and the rate of reinjury is high after return to normal work.⁶² Marginal tears of the DDFT are not always detected by ultrasonography, and tenoscopic evaluation of the DFTS is needed to determine the true extent of the damage.⁶³ The incidence is higher in the forelimbs than in the hindlimbs, and the tears occur more commonly on the lateral margin of the tendon.⁶³ After tenoscopic debridement or repair, the prognosis for ponies with marginal tears is considerably better than for those with focal core lesions.

Marginal tears of the SDFT and tears of the manica flexoria can also occur in ponies.⁶³ As in ponies with marginal tears to the DDFT, they are best diagnosed and treated tenoscopically.

Secondary mild thickening of the palmar (or plantar) annular ligament (PAL or PIAL) of the DFTS may accompany tears to the DDFT, SDFT, or manica flexoria. After tenoscopy and tendon debridement, it has been found that PAL desmotomy is not always necessary for a return to full soundness in ponies with such thickening.⁶³

Primary desmitis of the PAL is not uncommon in ponies, may be associated with tenosynovitis of the DFTS,

and can cause secondary stenosis of the fetlock canal.^{65,66} Desmopathy of the PAL or PIAL occurs more often in ponies and cob types than horses, especially in teenage ponies, and may be in part a degenerative condition. It occurs in hindlimbs more than forelimbs and results in a convex swelling on the palmar or plantar aspect of the fetlock, with localized heat and pain on palpation.⁶⁶ I have noted a higher incidence of plantar annular desmitis in ponies with chronic or repetitive laminitis. The condition may develop because of the postural and gait changes occurring with laminitis that put greater strain on the plantar structures of the fetlock joint. In such a situation, plantar annular desmitis could be described as a repetitive strain injury. Treatment initially should include anti-inflammatory therapy and treatment of the laminitis. In ponies that are unresponsive to treatment or have chronic PAL desmitis, desmotomy may be required to relieve fetlock canal stenosis. Chronic enlargement of the PAL can occur without signs of lameness.⁶⁵ However, ponies with lameness associated with PAL (or PIAL) desmopathy and asymptomatic enlargement of the PAL (or PIAL) of the contralateral limb may subsequently develop lameness in the second limb.

WOUNDS

Ponies undergoing second intention (contraction and epithelialization) wound healing are less likely to have excessive granulation tissue (*proud flesh*) than are horses, and wound contraction is generally faster.⁶⁷ In ponies, leukocytes produce more inflammatory mediators, resulting in better local defenses, faster cellular debridement, and a faster transition to the repair phase of wound healing. They also appear to have better myofibroblast organization.⁶⁸ An in vitro study has also found that horse limb fibroblasts have significantly less growth than those found in ponies.⁶⁹

OTHER CONDITIONS

The results of nuclear scintigraphic examinations of a limited number of athletic jumping ponies I have treated are similar to those described in horses⁷⁰ (i.e., increased technetium-99m [^{99m}Tc] uptake in the proximal and distal aspects of the proximal phalanx, dorsal spinous processes, and distal hock joints). As in the study in horses, not all of these lesions were associated with lameness and may represent bone adaptation to the act of jumping. In all ponies, the results of scintigraphy should be confirmed by diagnostic analgesia.

Back Pain

Back injuries in ponies, particularly involving the sacroiliac joint, appear to have a lower prevalence than in horses.⁷¹ Ponies, however, often demonstrate abnormal behavioral problems such as bucking, secondary to hindlimb and occasionally forelimb lameness, that can be perceived by the owner as signs of primary back pain.

Muscular Disorders

Recurrent exertional rhabdomyolysis (*azoturia* or *tying up*) does affect ponies, especially excitable types and ponies used for eventing. In general purpose ponies, recurrent

exertional rhabdomyolysis usually develops when the owner exercises an unfit pony. In one survey in the United Kingdom, ponies were the third most commonly affected group of horses affected by recurrent exertional rhabdomyolysis.⁷² Raised blood levels of creatine kinase and aspartate transaminase confirm the diagnosis, and treatment is similar to that for the horse. Polysaccharide storage

myopathy also has been reported in Welsh-cross ponies and in larger breeds of horses.⁷³

Cerebellar Abiotrophy

Cerebellar abiotrophy has been recorded in Gotland⁷⁴ and Eriskay ponies.⁷⁵ The disease is inherited in the Gotland pony as an autosomal recessive gene.⁷⁴

Chapter 127

Lameness in Breeding Stallions and Broodmares

Benson B. Martin Jr. and Sue M. McDonnell

Although maximal athletic fitness is typically not the goal for breeding stock, maintenance of musculoskeletal soundness is an important concern for breeding stallions and broodmares, especially because longevity is the usual expectation and a high percentage of these horses have existing musculoskeletal disease related to previous training and performance.

THE STALLION

Musculoskeletal fitness is critical to breeding efficiency of a stallion. The principal management goals are to maintain adequate fitness for normal breeding behavior and to avoid conditions or treatments that may adversely affect spermatogenesis or sperm viability. Libido, mounting, thrusting, and ejaculatory dysfunction represent major causes of poor breeding performance in stallions.¹ Musculoskeletal and neurological disease have been estimated to account for as much as 50% of these problems.^{1,2} The goal of managing a lame breeding stallion includes maintaining comfort and fitness to sustain libido and adequate copulatory ability.

Examination

Breeding stallions require skillful handling and are most efficiently examined in an area away from other stallions and mares, in a secluded area if possible. An experienced breeding stallion handler with appropriate restraint aids is ideal. Sedation can be used, but care must be taken not to confound the examination or jeopardize fertility. Phenothiazine tranquilizers, although useful for lameness examinations, have been associated with an increased risk of paralysis of the retractor penis muscle. If acepromazine is used, we recommend a small dose (5 to 10 mg intravenously 30 minutes before the examination) well before the horse gets excited, as well as diligent observation of the stallion for several hours to monitor its ability to retract the penis normally. Should the penis not retract with tactile stimulation once the horse is again otherwise

normally alert and reactive, steps can be taken immediately for physical support and management to minimize loss of erectile function.³ For further diagnostic procedures (e.g., radiography), xylazine or detomidine and butorphanol may be necessary.

History should include signalment, information about the performance career, duration and details of breeding experience, current problem and associated details, medical history, medication, nutrition, and environment, including housing, breeding facilities (e.g., flooring and dummy), and breeding protocol (semen collection technique and stallion handling). Knowledge of old performance-related problems is useful. During the breeding season, the veterinarian should determine the breeding schedule because this will influence the diagnostic and therapeutic strategy.

Complete musculoskeletal evaluation in a breeding stallion ideally begins with a routine breeding soundness examination, including a general physical examination, examination of the internal and external genitalia, evaluation of at least two ejaculates collected 1 hour apart, and evaluation of penile microflora, as outlined by the Society of Theriogenology.⁴

The veterinarian should observe the stallion at a walk and trot in hand, preferably on an even, hard, flat surface or on grass; perform upper and lower limb flexion tests of the forelimbs and hindlimbs because osteoarthritis (OA) is common; examine the feet with hoof testers; and palpate the back. Manifestations of back pain include abnormal sinking, prolonged muscle fasciculation or guarding, and contraction of the epaxial muscles without touching the back. Back pain is common during the breeding season because of the work or secondary to lameness.

A simple neurological examination should include observation of the horse moving in small circles to the left and right, walking in a serpentine pattern with the head elevated, and assessment of hindlimb strength by pulling the tail as the horse walks. The veterinarian should look carefully for unusual patterns of muscle asymmetry, possibly indicative of equine protozoal myelitis (EPM) if the horse is in, or from, North America.

A stallion often is examined because of difficulty in breeding and should be observed during teasing, mounting, thrusting, and dismounting. Specific findings suggestive of a musculoskeletal or neurological problem include failure to couple squarely and to thrust with smooth, rhythmic pelvic action; asymmetric hindlimb weight bearing, particularly one hindlimb dangling while thrusting with the other; failure to properly flex or use the neck or back; abnormal tail posture (spiked high) and anal tone (relaxed, voiding gas or feces) during thrusting; an anxious look in the eye or atypical ear postures suggesting discomfort or

distraction; failure to grasp securely with the forelimbs; lateral instability; falling during thrusting or dismount; weak, thready, or irregular ejaculatory pulses (often variable from day to day); and lameness after breeding.¹ Common manifestations of musculoskeletal pain are reluctance to mount or dismount, early dismount, squealing during dismount, or savaging the mare or handler during or immediately after mounting. Frame-by-frame videotape analysis may help to determine when discomfort occurs, as well as to identify handling factors that enhance or impair performance. Diagnostic analgesia can be difficult to perform and is often unnecessary because of the obvious signs of OA. Further investigation in selected stallions may include ultrasonography, nuclear scintigraphy, and measurement of creatine kinase before and 1 hour after breeding.

Specific Diagnostic Considerations and Therapy

Sore Back

A sore back is associated with inadequate coupling and thrusting during breeding. A stallion may fail to wrap the pelvis or neck around the mare or dummy and may tend to hold its head off the neck of the mare and paddle with the forelimbs. Thrusting is often of irregular depth and rhythm, that is, choppy and interrupted. An acutely sore back may become a chronic condition, exacerbated by breeding and an increased number of unsuccessful mounts, unless treated aggressively.

It is important to determine the primary cause of lameness and initiate the appropriate treatment. Pain can be secondary to another musculoskeletal cause such as OA, a heavy breeding schedule, poor footing, poor shoeing, poor fitting of the breeding dummy to the stallion, or allowing the stallion to advance up the side of a dummy mount so that it is thrusting with a curved back. Chronic back pain may be treated using acupuncture once weekly for 8 weeks and repeated every 3 to 4 weeks or as needed.⁵ Acupuncture therapy may be combined with nonsteroidal antiinflammatory drug (NSAID) therapy, or NSAIDs may be used alone.^{5,6}

Prognosis for normal breeding performance is guarded to good and varies with management factors. One key factor is ejaculatory efficiency. Once a stallion needs more than one or two mounts per breeding, expected performance diminishes rapidly.

Osteoarthritis

A stallion with OA appears stiff and painful during breeding; stiffness is often worse after rest and improves with exercise. The carpus, front fetlocks, and hocks are affected most commonly. Diagnosis may be obvious on physical examination and is confirmed radiologically.

Pain control is essential to maintain adequate breeding performance. We recommend phenylbutazone (1.5 to 2 g orally [PO] twice daily for 4 to 5 days and then 1 g twice daily for 5 to 7 days)⁷ combined with a period of sexual and general rest if possible. Clinically significant improvement may not be evident for up to 5 to 10 days. Long-term, low-dose phenylbutazone treatment has no measurable effect on sperm production or testicular size,⁸ but horses should be monitored for signs of toxicity, including colic, loss of appetite, diarrhea, dependent edema, and mucosal ulceration or renal disease.⁹ Other NSAIDs, such as flunixin

meglumine and ketoprofen, and intraarticular or systemic medication with corticosteroids, polysulfated glycosaminoglycans, and hyaluronan may be useful in selected horses.

Arthrodesis may be warranted for severe OA of the fetlock joint, but postoperative pain may persist, requiring long-term management. Pancarpal arthrodesis may be considered for stallions with severe carpal OA or after acute, severe carpal injury. With any lameness, pain management must be used to prevent increased recumbency, which can compromise thermal regulation of the testes, especially in hot conditions, and reduce sperm viability and fertility.

Neurological Disease

Neurological disease (see also Chapter 11) is usually evident during mounting, intromission, and thrusting, with a stallion stepping on its hind feet, bearing weight on a toe rather than the sole, and sometimes knuckling over. The stallion may bear weight unevenly during thrusting, sometimes becoming high sided on the mare or dummy mount, or falling. The stallion may have reduced proprioceptive control of the penis in seeking and intromission and may have poor anal tone during thrusting. The horse may require extraordinary effort to ejaculate.

Treatment of cervical vertebral malformation (CVM) in adult horses is challenging, and management methods are important, including good footing, proper shoeing, proper positioning of the mare or dummy mount, ground collection of semen, and pharmacological aids to ejaculation when necessary (Box 127-1).^{1,10} Special precautions must be taken during collection of semen or breeding to protect the stallion, the mare, and the personnel working around the stallion. The mare or dummy mount should be positioned to minimize the risk of a stallion with poor lateral stability falling. Lateral support can be provided at the hips. For semen collection, a mare that does not wiggle from side to side should be used. A dummy mount may be better but usually elicits less vigorous thrusting than a live mount and cannot be moved forward to assist the stallion with dismounting. Surgery occasionally is performed, with recovery taking many months.¹¹

The management of horses with EPM (see Chapter 11) is similar to that for horses with CVM, together with daily pyrimethamine and sulfadiazine or sulfamethoxazole for at least 60 to 90 days (Table 127-1). To prevent anemia, supplementation with folate and vitamin E is advised.¹² This treatment does not affect sperm production adversely.¹³

Sore Feet

Signs of sore hind feet include shallow thrusting, failure to plant the feet securely during thrusting, thrusting on one leg, and early dismount. Signs of sore front feet or other forelimb pain include hesitancy to mount and dismount. If not resolved quickly, sore feet can lead to long-lasting psychogenic sexual behavior dysfunction.

Many breeding stallions that come from the racetrack have poor hoof quality, underrun heels, long toes, and thin soles, predisposing them to sore feet. The feet should be observed daily and trimmed every 4 to 6 weeks. Leaving stallions barefoot is best, but some may require front shoes to remain comfortable. Rarely, bilateral hind foot pain can cause similar clinical signs, and hind shoes with corrective

BOX 127-1

Management and Pharmacological Aids to Enhance Libido and Facilitate Ejaculation

Management Aids

To enhance sexual arousal

Prolonged teasing under conditions that yield the highest safe level of arousal
Breeding schedule for maximum arousal
Natural estrus stimulus and mount mare
Stable (no side-to-side movement) mount mare or dummy is necessary
Minimal distractions in the breeding area
Established breeding routine rich with conditioned stimuli for maximum arousal
Encouragement and positive reinforcement

To reduce back and hindlimb pain and accommodate musculoskeletal deficiencies

Mount mare or dummy of appropriate height and conformation
Mare or dummy down grade from stallion to reduce weight on hindlimbs
Semen collection on the ground (artificial vagina or manual stimulation)
Weight loss to reduce work of hindlimbs, particularly during breeding
Pain treatment
Lateral support at the hips during mount
Good footing (grass or dry nonslip, synthetic surface)

To increase positive stimulation of the penis

Pressure and temperature of the artificial vagina that yields best response
Hot compresses applied to the base of the penis

Pharmacological Aids

To enhance sexual arousal

Gonadotropin-releasing hormone: 50 µg of Cystorelin SC 1 and 2 hours before breeding²³

Diazepam: 0.05 mg/kg slow IV administration^{24,25}

To lower ejaculatory threshold (in copula)

Imipramine: 500 to 1000 mg PO in grain^{31,32}

To induce ejaculation (ex copula)

Imipramine: 2.2 mg/kg PO followed 2 hours later by xylazine: 0.4 to 0.6 mg/kg IV^{33,34}

SC, Subcutaneously; IV, intravenous; PO, orally.

trimming may be necessary (Editors). These horses may be left barefoot during the off season to allow the feet to grow more normally. Provision of soft footing in the breeding shed and weight control are important. Pain control using NSAIDs may be necessary.

Fractures of the Distal Phalanx

Fractures of the distal phalanx can be acute or chronic injuries. Most are palmar process fractures, and horses can be managed with a bar shoe with side clips reset every 6 weeks, stall rest, and NSAIDs. Sagittal fractures of the distal phalanx are more serious, but horses may be managed in the same way.

Laminitis

Common primary causes of laminitis include contralateral orthopedic injuries, colitis, Potomac horse fever, *Salmonella*, and other infectious diseases that predispose to the release of endotoxins. The treatment of horses with acute laminitis includes treating the primary disease, supporting

TABLE 127-1

Medications			
DRUG	DOSE	ROUTE	FREQUENCY
Phenylbutazone	2.2 mg/kg	PO, IV	BID
Flunixin meglumine	1.1 mg/kg	IV, IM	BID
Ketoprofen	1.1 mg/kg	IV	SID
Aspirin	15-100 mg/kg	PO	SID
Isoxsuprine	1.2 mg/kg	PO	BID
Methocarbamol	40 mg/kg	PO	BID
Sulfamethoxazole	12.5 mg/kg	PO	BID
Sulfadiazine	12.5 mg/kg	PO	BID
Pyrimethamine	1 mg/kg	PO	SID
Folate	0.5 mg/kg	PO	SID
Vitamin E	5000 IU	PO	SID
Xylazine	150 mg	IV	AN
Detomidine	5-10 mg	IV	AN
Butorphanol	10-25 mg	IV	AN
Acepromazine	10-25 mg	IV	AN

the distal phalanx, decreasing blood pressure, treating inflammation, and managing pain (see Chapter 34).¹⁴⁻¹⁶

Chronic laminitis, with rotation of the distal phalanx, can be an important problem in breeding stallions, manifested as a stiff gait or more overt lameness in one or both front feet. Trimming, shoeing, and providing analgesia are important (see Chapter 34).

Muscle Disease

Rhabdomyolysis and other muscle diseases are usually evident during or after thrusting. Inefficient thrusting on early mounts is followed by increasing discomfort, leading to rapid mounting and dismounting. The horse may sweat profusely and have an increased respiratory rate and obvious pain. Treatment during an acute episode includes administering acepromazine (10 to 20 mg intravenously) to control anxiety and 10 to 20 L of balanced electrolyte solution intravenously, keeping the horse confined to a stall, monitoring progress, and evaluating the stallion closely for paraphimosis. In horses with chronic rhabdomyolysis, the diet should be altered to primarily hay and high-quality, low-protein, low-carbohydrate feed.¹⁷ Methocarbamol (see Table 127-1) is useful in some horses.

Injuries

Injuries in stallions, including lacerations, punctures, abrasions, and fractures or dislocations, are managed similarly as in other horses. A common injury is abrasion or contusion of the carpus during mounting, especially with dummy mounts. A stallion with a painful carpus may fail to grasp a mare with the forelimb and may stand up on the mare or dummy. Sexual rest until the wound heals is usually best. If continued breeding is necessary, emollient topical analgesic ointment and skillful bandaging from the coronet to several centimeters above the carpus can relieve apparent discomfort, with the administration of NSAIDs if required.

Hyperextension injuries of a forelimb may occur at dismount but are usually not serious and resolve with NSAID treatment.

Aortoiliac Thrombosis

Signs suggesting aortoiliac disease include delayed ejaculation despite good libido (numerous mounts and more than 12 thrusts); progressive hindlimb weakness or pain during thrusting resulting in camping under the mare or dummy; and difficulty backing up to dismount.¹⁸ Erection aberrations are not as common as ejaculatory dysfunction, but they can include delayed or rapid tumescence or detumescence, or loss of erection during thrusting.

Comprehensive Management

The useful breeding career of a stallion with lameness problems often can be prolonged substantially with coordinated veterinary care and breeding management. Particular concerns and challenges include the following:

1. Controlling pain without adversely affecting libido or fertility
2. Maintaining a level of fitness adequate for the breeding work without exacerbating lameness
3. Using available management and veterinary techniques to enhance libido and ejaculatory function, to reduce the work of each breeding, and to reduce the total number of breedings required over the season
4. Managing the breeding book to maximize breeding value while not exacerbating the lameness

Pain Management

Phenylbutazone is the most common NSAID used for breeding stallions. A 4-week oral treatment course (2.2 mg/kg twice daily) has no adverse effects on semen quality at the time of ejaculation or after 24 and 48 hours stored at 4° C.⁸ Although fertility trials have not been done, clinical experience suggests no adverse effects of chronic treatment with phenylbutazone at levels tolerated well by a stallion. We recommend orally administered phenylbutazone daily throughout the breeding season to keep the stallion comfortable and functioning with as little effort and pain as possible to avoid a potential downward spiral of delayed ejaculation, additional effort, and exacerbated lameness.

Firocoxib is now available for horses. Although not specifically tested in breeding stallions, efficacy for lameness has been reported to be similar to that of phenylbutazone.¹⁹

We have used gabapentin clinically in combination with phenylbutazone in an attempt to help breeding stallions with possible neurogenic and musculoskeletal discomfort.²⁰ Early studies indicate that oral bioavailability of gabapentin is low compared with intravenous administration but is well tolerated at 20 mg/kg.²¹

Complementary pain management, including acupuncture,^{5,6} electrostimulation, and massage therapy, may provide additional comfort, with no adverse effects, on semen quality or fertility.

Fitness and Weight Management

Routine exercise is one of the most important management factors for maintaining cardiovascular and musculoskeletal physical and mental fitness of any breeding stallion. A general recommendation for exercise for a sound breeding stallion is daily paddock exercise for a minimum of 8 hours or a minimum of 30 minutes of supervised exercise or light work. Although the common tendency is to rest a lame horse, controlled exercise is probably even more important for breeding efficiency of a lame stallion. A daily exercise

program, including turnout or supervised light work, appears to clinically significantly improve the breeding efficiency of a lame stallion. The type of exercise is influenced by the degree of lameness and the temperament of the stallion. Controlled exercise may include daily riding, lunging, jogging, swimming, or exercise on a treadmill or mechanical walker.

Libido and breeding efficiency almost always improve with a stallion carrying less rather than more body weight, particularly for hindlimb lameness or incoordination. We have seen remarkable improvement in breeding efficiency and stamina after reduction in body weight in Quarter Horses with small sore feet or in stallions with aortoiliac thrombosis.

Breeding Management and Handling

Breeding Schedule

For any hand-bred stallion, and particularly for a stallion with lameness, an important goal of breeding management is to minimize the work of each breeding and the cumulative work of the season. For heavily booked stallions, total seasonal work can be reduced and efficiency of each breeding often can be improved by limiting services to one per mare cycle. This forces upgraded mare management so that she is close to ovulation when covered. This type of mare tends to be more stimulating to the stallion and to stand more solidly for breeding. For certain stallions with smaller books, availability for service often can be limited to one mare, 3 or 4 days weekly. In our experience, by shifting effort toward mare management and effectively increasing the sperm numbers per service, seasonal pregnancy rates are often as good as or better than with more frequent services.

For stallions that are breeding by artificial insemination, with good to excellent longevity of sperm motility, a reasonable book of mares can be served with collection of semen limited to two or three times weekly. For stallions in registries permitting frozen semen, it is helpful to bank frozen semen for consideration for use during busy periods or to reduce pressure for obtaining fresh ejaculates when problems arise.

Maintaining Ideal Levels of Libido

It is important to maintain good to high libido to help a stallion to ejaculate more efficiently in the face of pain, neurological dysfunction, or musculoskeletal disability. Well-tested management schemes and pharmacological aids are available to enhance libido (see [Box 127-1](#)). The most useful management tools in a stabled stallion are housing near mares and away from stallions and ample daily teasing exposure to mares.²² Treatment with gonadotropin-releasing hormone can be useful to boost libido via increased circulating testicular steroids.²³ Diazepam, by inhibiting the memory of pain associated with breeding, may be helpful.^{24,25}

Occasionally, rowdy or overenthusiastic breeding behavior complicates management and breeding of a lame stallion. The stallion handler should use judicious correction and guidance to establish and maintain organized control, without overcorrection that will diminish libido.²⁶ Medication is not recommended because tranquilization at a level effective to control behavior makes the stallion unstable for breeding, and using progesterone

or other endocrine-mediated treatments adversely affects spermatogenesis.

Breeding Shed Handling Considerations

Most disabled stallions benefit from having the mare or dummy mount slightly down grade. This can reduce the work of the hindlimbs in supporting the body weight. For a live mount mare, a down grade is achieved best with a sloping ramp extending at least 3 m behind, in front, and to each side of the mare (Figure 127-1). A height differential between the stallion and the mare can be built with mats or by placing the mare in a pit. These work well if the mare remains stationary, but if the mare moves back, the grade may be reversed for the stallion. If the mare moves forward, the stallion can become trapped between the mare and the front edge of mats, or in the pit with the mare. When breeding a stallion with the mare downhill, it is important to avoid the peak of a knoll that slopes off to the sides,

Fig. 127-1 • Mare positioned down grade for breeding.

behind the stallion, or in front of the stallion. This sets the stallion up to fall sideways should the mare move sideways or to be at further disadvantage if the mare moves backward. Once the stallion mounts, restraint of the mare should be optimized to reduce movement in any direction. Disabled stallions that are tentative to mount also can be deterred by low ceilings, cornered mares, or dummy mounts.

When using a dummy mount for stallions with hindlimb, back, or neck problems, we find that greater heights are better. Most disabled stallions do better when guided to remain mounted squarely from the rear, as opposed to across the dummy, or traveling up the side. This is best accomplished by securing the artificial vagina at a physiological angle against the dummy for the stallion to serve, rather than taking the artificial vagina to the horse.

Excellent footing in the breeding area, which is customized to a stallion's particular needs, can improve breeding efficiency greatly (Table 127-2). The surface should be nonslip even when wet, seamless and even to avoid stumbling, and provide moderate cushion. Stallions with hindlimb weakness or incoordination tend to camp under the mare. For these stallions the footing behind the mare is critical to maximize the ability to correct the stance. Although some cushion is good, it should not be so spongy or deep that the stallion gets caught up or buried in the substrate. Stallions with sore feet, especially front feet, benefit from a softer footing, particularly a soft landing during dismount. Heavy sod on well-drained soil is often the simplest and best outdoor footing. Composite rubber athletic surfaces, particularly if poured and seamless, make ideal breeding surfaces.

A stallion should be given ample freedom about the head, particularly during mounting and thrusting, to allow

Fig. 127-2 • Spotting a stallion on the left side during breeding.

postural adjustments. Enforcing routines that work well for sound stallions, such as always keeping the head on the left side of the mare or dummy mount, may discourage a disabled horse. For severely ataxic, weak, or uncomfortable stallions, thrusting and ejaculation can be facilitated with gentle stabilizing assistance or spotting during breeding. We recommend an assistant apply gentle pressure with the hands on one or both hips to support the stallion from falling (Figure 127-2). Some stallions tolerate support from the rear, for example, with a wide strap held from either side behind the buttocks. Some resent this type of support, appearing to become trapped on the mare.

Gentle, guiding handling during dismount is important for all stallions but particularly for a disabled horse. For stallions with hindlimb weakness, pain, or incoordination, special consideration should be given to allowing the stallion as much recovery time as possible before dismount and to moving the mare slowly out from under the stallion rather than forcing the stallion to back off. Ataxic stallions that tend to step on themselves and the mare while breeding can benefit from simple, well-secured protective boots or wraps for themselves and the mare.

Monitoring Breeding Performance

Stallions with chronic musculoskeletal discomfort or disability usually deteriorate, and breeding performance should be monitored systematically so that adjustments can be made to maximize performance. A sensitive measure of improved comfort is the number, rhythmic pattern, and strength of pelvic thrusts from insertion to ejaculation. Normal, sound stallions typically require seven to nine thrusts at about 1-second intervals, with even sweep and strength, to ejaculate. The normal range of mount duration is 20 to 30 seconds, with insertion time 12 to 20 seconds. With discomfort, horses tend to require more thrusts, the sweeping pattern of the thrusts becomes less organized (irregular depth, rhythm, and strength), and the hindlimbs become more dancy as opposed to being planted with equal weight bearing on each. The head and ear positions of an uncomfortable stallion also suggest distraction (as if about to quit, fall, or dismount) as opposed to commitment. Horses with sore backs or necks tend to fail to couple closely. Thrusts may be jerky and shallow. Stallions with

hindlimb neurological deficits may bear weight unevenly, become camped under, or become tipped toward the stronger side, with the weaker hindlimb dangling. They seem particularly unable to maintain lateral stability. We recommend developing a customized record sheet for daily grading of each abnormality. Videotaping each breeding from a direct lateral view that spans the entire mount and stallion and from the rear provides the most complete record.

One Mount Rule

For longevity of a disabled stallion through a season or through a breeding career, we recommend that ejaculation should be achieved with one mount. If a horse does not ejaculate in one or at most two mounts, the horse should be taken back to the stall or paddock to rest and return fresh. This strategy often effectively yields a greater number of successful mounts, provided that conditions are optimized for the first mount. The horse should be at the highest level of arousal possible for safe handling, the mount well positioned and optimally restrained if it is a live mare, the artificial vagina at optimum pressure and temperature for semen collection, and the handling team in top form and focused. If particular procedures or medications (see Box 127-1) are known to make the horse more comfortable, enhance libido, or reduce the ejaculatory threshold, we recommend using these from the start.

Ground Semen Collections

For stallions that breed by semen collection, a valuable alternative to mounting is ground semen collection. Most stallions with good to excellent libido are excellent candidates for semen collection while standing on the ground or even while supported in a sling. This technique is particularly useful in horses with aortoiliac thrombosis, cervical vertebral malformation, EPM, and other conditions with hindlimb instability or weakness.

Pharmacologically Induced Ex Copula Ejaculation

For stallions that breed by artificial insemination, pharmacologically induced (or chemical) ejaculation can be used with the stallion at rest in his stall. Currently the generally most effective treatment (50% to 70% of attempts) is a combination of imipramine hydrochloride administered orally about 2 hours before intravenously administered xylazine hydrochloride (see Box 127-1). For a particular stallion, best results can be achieved by titrating through a range of doses for each component drug.

BROODMARE

Soundness of a broodmare is important for the demands of pregnancy and lactation and for ongoing comfort for normal expression of estrus behavior, willingness to stand for natural service when necessary, conception, and normal interactive maternal behavior.²⁷ Diagnosis and treatment should not adversely affect fertility or the safety of the developing fetus, or nursing foal. As a population, broodmares tend to have a high rate of husbandry-related feet and limb problems. They may have old training or racing injuries. Broodmares coming and going tend to have herd social aggression and related injuries. Broodmares also suffer lameness secondary to foaling.

Specific Diagnostic Considerations and Therapy

Sore Feet

It is recommended that maiden mares should arrive on a breeding farm at least 8 to 10 weeks before the beginning of the breeding season. This allows time to assess and monitor condition of the feet and time for trimming as needed. Early arrival also affords time to acclimate the horse to the farm routine and social environment and for advanced photoperiod manipulation (under lights). Simple sore feet are a common problem in a maiden mare coming from the racetrack. The mare may have thin-walled feet and soles, underrun heels, long toes, bruised feet, quarter cracks, or corns. The mare may have been shod for a long time and not be accustomed to being barefoot. If sore feet are suspected as a cause of lameness, the feet should be examined with hoof testers. Baseline radiography may be indicated. Soaking, poulticing, sole painting, and the administration of phenylbutazone or flunixin meglumine (see Table 127-1) may be required for effective management of mares with foot soreness. Feet of broodmares should be trimmed every 6 to 8 weeks and ideally mares should be barefoot on all limbs and certainly for the hindlimbs.

A subsolar abscess is the most common cause of acute foot pain (see Chapter 28). Other causes include a sequestrum, laminitis, or a fracture of a palmar process of the distal phalanx. A sequestrum of the distal phalanx may be removed in a standing horse,²⁸ eliminating the risks of general anesthesia for a developing fetus.

Laminitis

Acute or chronic laminitis can be a management problem in mares and may be secondary to pleuritis, diarrhea, severe lameness, or most commonly after foaling followed by a retained placenta (more common in draft breeds; see Chapter 125) or infectious metritis. Chronic laminitis also occurs in overweight mares, mares with a previous history of laminitis, or those that have ingested large amounts of feed or fresh pasture. Acute or chronic laminitis can have a negative effect on fertility secondary to pain.²⁷

The treatment goals in broodmares with acute laminitis and chronic laminitis are similar to those described for the stallion. In our experience, some mares with chronic laminitis can be salvaged as successful broodmares with careful foot care, pain medication, good footing, separation from other broodmares and associated competition, and management similar to that described for the breeding stallion. In addition, some can conceive and deliver a normal foal, if these management techniques are successful. However, reproductive lives are often limited by laminitis.

Osteoarthritis

A broodmare with OA may need confinement to a stall or small paddock and analgesic medication (see Table 127-1). With severe OA of the fetlock or carpus, arthrodesis may be considered as a last resort in a broodmare that can no longer conceive or maintain a foal because of chronic pain.

Enlarged or Swollen Limbs

Palmar or plantar dermatitis of the pastern (scratches or mud fever) secondary to wet or muddy footing may cause lameness, particularly in hindlimbs. The mare should be removed from the wet area. Local therapy may be

necessary, including washing, drying, and clipping the affected area and local application of a steroid/triple antibiotic topical ointment.

Lymphangitis is seen most commonly in the hindlimbs, is worse in later pregnancy, and causes reluctance to move, painful and pitting edema, and fever. Treatment includes stall rest, antibiotic therapy, and phenylbutazone.

A puncture wound and secondary cellulitis may cause lameness. Locating the original wound is often difficult. Aggressive antibiotic and antiinflammatory therapy is necessary. Additional treatment may include surgical drainage, hot packs, warm water hosing, and bandaging.

Hindlimb lameness may be associated with mastitis. The udder is painful to touch; the mare may not allow the foal to nurse; her appetite may decrease; and she may be febrile. Lameness resolves with symptomatic treatment of the mastitis.

Rhabdomyolysis

Acute rhabdomyolysis occurs occasionally in late gestation after particularly vigorous exercise. The mare may not come in for normal feeding or night stables and is often anxious, has a stiff walk, and may have dark-colored urine. Diagnosis is confirmed by measurement of serum creatine kinase levels. Treatment includes stall rest and NSAIDs. A mare with a foal at foot can be treated with the foal present.

Foaling-Related Injuries

Obturator nerve paralysis secondary to dystocia can result in mild to severe lameness. The mare may show difficulty in abducting the hindlimb and standing immediately after foaling. Femoral nerve paralysis secondary to dystocia results in inability to fix the patella and therefore the hindlimb. This is seen immediately after foaling. Symptomatic therapy for either condition includes NSAIDs, supportive therapy, nursing care, such as slinging if necessary, and adequate bedding and footing. The prognosis for full recovery is guarded, and a nurse mare may be needed for the foal.

Prepubic tendon rupture or ventral body wall hernias may occur during late gestation, apparently without reason. Ventral edema cranial to the udder is severe, unilaterally or bilaterally. An affected mare may have difficulty rising. It is difficult to obtain an accurate diagnosis until edema resolves after foaling. The body wall enlarges in the ventral flank. Diagnostic tests include palpation per rectum and ultrasonography. Occasionally, a tear in the ventral body wall can be palpated per rectum. Supportive treatment consists of NSAIDs, physical support of the enlarged area using large bandages, restricted exercise, close monitoring before and during foaling, a laxative diet, and assisted early induction of foaling. Successful surgical repair of ruptured prepubic tendons and large ventral body wall hernias is often unrewarding, but smaller defects can be repaired successfully. The prognosis for mares with large tears of a ruptured prepubic tendon and future use as broodmares is guarded to poor.²⁹ Embryo transfer may be a reasonable alternative in breeds that allow this form of management (the Editors).

Neurological Disease

The most common neurological disease of adult broodmares in the United States is EPM. Cervical vertebral malformation also occurs and should be distinguished because

treatment is different. Treatment for EPM is as for a stallion, but folate supplementation is not recommended in broodmares receiving pyrimethamine because of the potential alteration in organogenesis.³⁰

Old Injuries

Many broodmares have old superficial digital flexor tendon or suspensory ligament injuries that may deteriorate, or mares may sustain acute reinjury. Aged broodmares may have gradual thickening and lengthening of the hindlimb suspensory ligaments. Broodmares with acute reinjuries are treated by restricted exercise, analgesia if needed, local therapy, and ultrasonographic monitoring. Stall confinement with daily handwalking may be needed for 3 to 4 months, depending on ultrasonographic evidence of healing. Treatment of mares with hindlimb suspensory desmitis with a dropped fetlock consists of strict stall confinement, pain medication if needed, and application of an extended heel, egg bar shoe. This shoe should be removed just before foaling for safety.

Occasionally, older broodmares develop extensive new bone, especially around the carpus, causing lameness. The mare should be separated from the normal herd to reduce competition for food and water, with restricted exercise and analgesia provided.

General Husbandry and Breeding Management Considerations

Simple management and handling may improve the comfort of an acutely lame broodmare and prolong the useful life of a chronically unsound broodmare. Attention to social groupings can reduce the chance of new injury and provide greater comfort for an older or lame broodmare. Many farms separate broodmares into compatible groups, including maidens, seasoned broodmares, barren mares, and older broodmares. The goals should be to limit competition for food and water and to minimize risk of encountering manufactured obstacles during aggressive interactions. Some farms follow a buddy system, in which

compatible pairs are kept together as much as possible. Convalescent broodmares often do well grouped together for rehabilitation or special medical attention. Good footing, including breeding areas, pastures, alleyways, areas around hay bunks, loading ramps, and in stalls, can prevent injury and provide comfort for a lame broodmare. Broodmares benefit from as much exercise as possible to maintain overall good musculoskeletal fitness, and obesity should be avoided.

Phenylbutazone is the most commonly used drug for the effective pain management and has limited or no effect on organogenesis. Its use may be associated with gastric ulceration and concurrent treatment with omeprazole (4 mg/kg curative or 2 mg/kg preventative) may be of value, although any effects on organogenesis have not been reported.

Emergency surgery to repair a fracture may be necessary to save the life of the mare and fetus. Ideally a preformed plan should be in place, especially close to gestation. Is the decision to save the mare and the foal or to consider a nonsurvival cesarean section to deliver the foal? If the decision is made to proceed to save the mare and fetus, administration of synthetic progesterone (30 mg/kg PO twice daily) may be helpful, especially in the first trimester of pregnancy. Elective surgery should be delayed until the mare has foaled whenever possible.

For lame or otherwise disabled mares, artificial insemination should be considered whenever possible. For natural cover, we recommend excellent footing, a gentle approach, reduced restraint, and acute pain control. To reduce the stress in broodmares with pain, maiden mares, or broodmares with a known volatile live cover breeding history, the use of 25 mg of acepromazine and 10 to 25 mg of butorphanol given together intravenously 15 to 20 minutes before breeding may increase safety without the ataxia or sudden outbursts seen with xylazine administered alone. When possible, medication, including nutritional supplements, should be avoided during gestation and early lactation, including detomidine and xylazine used alone.

Chapter 128

Lameness in Foals

Robert J. Hunt

Like all horses, foals are prone to injury and lameness; however, considering the immature and fragile musculoskeletal system, the incidence of serious injury is surprisingly low. Exposure of a foal's naive immune system to the array of pathogens places the foal at high risk of infectious causes of lameness. Degree of lameness in foals ranges from subtle and nearly imperceptible to non-weight bearing. Although no published studies document the incidence of lameness in foals, the economic impact on the horse industry is substantial when factors such as cost of diagnosis and

treatment, long-term morbidity and mortality, and the effect on athletic potential are considered. Economic and emotional losses may be substantial for horse owners and breeders, enough so that they may abandon the horse industry. Most lameness is self-limiting, however, and in many instances early recognition and prompt treatment makes a difference in costly medical bills and improves the long-term soundness or survival. It is imperative that veterinarians learn to recognize the early clinical signs of these serious disorders and to initiate prompt treatment. Clients should be made aware of the potential danger of a wait-and-see approach and a delay in treatment.

EVALUATION OF A LAME FOAL

Foals often resist handling and limb manipulation, making assessing responses difficult and potentially confusing. It is imperative that the veterinarian is patient when evaluating foals. The basics of lameness localization are the same as

in adult horses. The stance and any obvious swelling or sensitive areas on palpation should be noted. It is important to palpate the contralateral limb to gauge the foal's response to manipulation of that limb. Hoof and limb temperature (hot or cold) and digital pulse amplitude should be evaluated. Detailed assessment with hoof testers is invaluable in differentiating causes of hoof lameness. Any aberration in hoof development (e.g., club foot, deformed foot, unbalanced feet, or mismatched sizes of feet) should be noted. Postural or conformational changes, including sudden angular limb deviation, limb laxity, or contraction, may result from altered load bearing associated with lameness or from structural changes from injury. Careful palpation of all structures of the skeletal system, including all palpable surfaces of joints, bones, digital flexor tendons, and ligaments, with the foal in a standing position and with each limb flexed is important. Swelling should be differentiated as intraarticular, periarticular, or both.

Gait deficits in foals manifest like those in adult horses in that lameness is expressed as reduced time or weight on the lame limb.¹ The phase of the stride in which the gait is altered is the result of reducing loading of the limb during the painful portion of locomotion. Foals are more likely to show lameness in dramatic fashion by carrying a limb (i.e., not bearing weight) or exaggerating efforts to reduce load on the limb. It is important to observe the foal at a walk to discern subtle differences in stride and foot placement that may be missed at a trot.

Routine ancillary diagnostic tests used in foal lameness evaluation include diagnostic analgesia; radiographic, ultrasonographic, and nuclear scintigraphic examinations; and arthrocentesis and aspiration of other fluid pockets.¹⁻⁴ Diagnostic analgesia should be a routine component of lameness localization in foals just as in mature horses, unless a fracture is suspected. Any areas of suspect pathological bone conditions should be evaluated radiologically. Weekly follow-up radiological evaluation may be required to recognize bony changes. Soft tissue evaluation is aided by ultrasonography, especially when the veterinarian is looking for fluid pockets or alterations in soft tissue architecture. Nuclear scintigraphy has limited applications for skeletal evaluation in foals because normal radiopharmaceutical uptake in the physes can confuse or mask subtle abnormalities.

NONINFECTIOUS CAUSES OF LAMENESS

Noninfectious causes of lameness include external and internal traumatic injuries and developmental or metabolic musculoskeletal diseases. Lameness also may result as a sequela to vascular disorders or may be immune-mediated secondary to an infectious problem.

Lameness resulting from external trauma varies with the area involved and the severity of the injury. Essentially any portion of the skeletal system is prone to injury. Traumatic injuries resulting in lameness are common but fortunately self-limiting in most instances. Boisterous activity, coupled with a hazardous environment, places a foal at an increased risk of sustaining injury compared with an adult horse. Trauma from other horses (a mare kicking a foal or collision injuries with other foals) is a common cause of lameness. Impact with stationary objects while a foal is being chased may result in serious injury. Internal trauma

Fig. 128-1 • Typical crouched stance of a foal with rupture of the left gastrocnemius muscle subsequent to overextension while chasing a mare. The foal is unable to extend the limb or support full weight on it. Note the excessive flexion of the hock.

includes overexertion injuries, such as a foal running excessively with a mare or being chased, resulting in fracture of the proximal sesamoid bones (PSBs), or rupture of the suspensory apparatus or other soft tissue structures (Figure 128-1). Common fractures in foals include those involving the long bones, physes, PSBs, carpal and tarsal cuboidal bones, and the distal phalanx.^{1,2,5,6}

Fractures of Long Bones

Clinical evaluation may be diagnostic in foals with lameness of traumatic origin. Unstable fractures or severe soft tissue injuries cause obvious, immediate clinical signs. If a fracture is suspected, radiographs are necessary to confirm the diagnosis and determine the severity of the injury (Figure 128-2).

Fractures of long bones most often result from external trauma such as a kick or having the limb pinned beneath an object while rolling. A limb misloaded while rearing may result in fracture of the tibia, femur, or pelvis. If a limb is unstable distal to the femur or humerus because of a fracture, the limb should be immobilized before transport. Surgical approaches and repair techniques for individual fracture types are described elsewhere.

Prognosis for a foal after fracture depends on anatomical location of the fracture; the complexity, orientation, and degree of soft tissue injury around the fracture; and whether the fracture is open. Secondary problems associated with prolonged lameness or confinement and immobilization often dictate the degree of long-term soundness. These problems include excessive laxity of the metacarpophalangeal or metatarsophalangeal joint, varus deviation, or deformity of the foot, such as an underslung or crushed heel and overgrowth of the toe. Mechanical laminitis is not as common as in adult horses, but it does occur. Contraction or excessive laxity of the fractured limb associated with disuse may prevent future soundness.

Fig. 128-2 • Slightly oblique lateromedial radiographic image of the femur of a foal. There is an unstable, displaced fracture of the distal aspect of the femur, the result of trauma. This is a Salter-Harris type II fracture.

Fractures of the radius, ulna, and tibia are generally more amenable to surgical repair than are femoral and humeral fractures. If economics do not allow surgery, conservative management of foals with femoral and humeral fractures by stall confinement is a feasible alternative to surgical intervention. Teaching the foal to support its weight on a straw bale or butt bar may alleviate load on the contralateral limb for hindlimb fractures. Complications encountered after surgical repair of femoral or humeral fractures, such as implant failure or infection, are usually fatal. Without postoperative complications, however, a foal has a greater chance of soundness for light athletic use with surgical management. Fractures of the radius and tibia require surgical stabilization if any displacement of the fracture is present. Most foals have a fair to good prognosis for light to medium athletic use or for breeding purposes. Foals with fractures of the ulna that have any displacement should undergo surgery, but those with nondisplaced fissure fractures do not require surgical fixation. Foals with nondisplaced fractures of the ulna should have stall confinement for a minimum of 8 to 10 weeks and undergo radiological monitoring every other day for the first 2 weeks and then weekly to ensure displacement does not occur. Foals with displaced, unstable fractures of the metacarpal and metatarsal bones generally have a guarded to poor prognosis for future athletic use, with or without surgery. Foals with simple, stable fractures of the metacarpal and metatarsal bones not requiring surgery have a good prognosis.

Fractures of the Pelvis

Pelvic fractures in foals are common and usually results from a foal misloading a hindlimb when rearing or from flipping over and landing on one side. Gait and degree of lameness depend on the portion of the pelvis involved and the amount of trauma to the surrounding tissue. Common sites of injury include the tuber coxae, tuber ischium, acetabulum, and the shaft of the ilium. Deep palpation of the area may elicit pain.

The characteristics of the lameness may reflect the site of injury. A foal with a fracture of a tuber ischium is reluctant to advance the ipsilateral hindlimb and has a shortened cranial phase and prolonged caudal phase of the stride. As with many pelvic injuries, the tail often is elevated and held to the opposite side, and the foal may carry the limb when running but bear full weight while walking. Conversely, foals with fractures of a tuber coxae have a shortened caudal phase of the stride, and the injured tuber coxae is often lower than the contralateral side.

Treatment for foals with pelvic fractures includes confinement for 8 to 12 weeks followed by a gradual return to controlled exercise. Improvement in the degree of lameness should be seen within 2 to 3 weeks, depending on the region of the pelvis injured. Foals with acetabular injuries may require a longer duration of confinement before improvement is seen. If the foal is fully weight bearing, controlled walking for short periods after 3 weeks can be started if the foal is tractable.

Prognosis for foals with pelvic fracture not involving the acetabulum is fair to good for light use but guarded for competitive athletics. Some horses are able to race following healing of pelvic fractures. Most foals with pelvic fractures involving the acetabulum have a poor prognosis for an athletic future; however, they generally survive to make breeding animals. In the Editors' experience, the prognosis for athletic function is not invariably poor because, in contrast to adult horses, foals have a remarkable capacity for bone remodeling, and even some severe articular fractures can heal satisfactorily, allowing normal athletic function.

Fractures of the Physes

Physeal fractures have been categorized and defined using the Salter-Harris classification scheme.²⁻⁷ A type I fracture occurs through the physis and involves only the zone of hypertrophied chondrocytes; the adjacent epiphysis and the metaphysis are not involved. A type II fracture occurs across the physis and extends into a portion of the metaphysis. A type III fracture involves the physis and epiphysis and extends into the joint. A type IV fracture includes involvement of the physis, epiphysis, and metaphysis. A compression injury to the physis is referred to as a type V fracture. This classification scheme is applicable to pressure physes that contribute to the longitudinal growth of bone and are subject to compressive forces. Traction physes, such as the olecranon growth plate, are subject to tensile forces and are not included in this classification scheme.

Physeal fractures are common because physeal bone is weak compared with diaphyseal bone. Diagnosis of physeal injuries is made on clinical and radiological findings (Figure 128-3). Clinical signs include varying degree of lameness, pain on palpation of the injured area, swelling, and possibly instability of the limb or angular deviation of the limb

Fig. 128-3 • **A**, Marked carpus valgus deformity of the right forelimb as a result of a distal, radial physal fracture. Note also the slight varus deformity of the left carpus. **B**, Dorsopalmar radiographic image of the right carpus. Lateral is to the right. There is a displaced Salter-Harris type III fracture of the distal radial physis. Note the widening of the physis medially, resulting in the valgus deformity.

distal to the fracture. The primary differential diagnosis for a stable physal fracture is infectious physitis.

Surgical repair is necessary in foals with displaced, unstable physal fractures. The major difficulty in surgical stabilization is the short section of epiphysis available for purchase. This shortcoming generally is overcome with the use of a form of T-plate, cross pins, transfixation pins, or tension-band wiring. If adequate reduction and stability are achieved, the prognosis for future soundness is good.

Cuboidal Bone Injury

Injury to the cuboidal bones of the tarsus or carpus often is associated with failure or delay of endochondral ossification in premature or dysmature neonates.^{5,6} Crushing and malformation of the soft cartilaginous precursors of the cuboidal bones result in osteoarthritis and varying degrees of lameness (Figure 128-4). Outwardly the limb may appear normal or have an angular deviation, or, if a hindlimb is involved, it may be sickle hocked or curbed. Attempts at prevention of this condition are more effective than treatment after its onset, although these are limited in effectiveness. Prolonged stall confinement of premature neonates is recommended until radiological signs of ossification of the cuboidal bones occur. Ossification generally requires 4 to 8 weeks but may vary. Foals affected with crushing of

cuboidal bones rarely make competitive athletes, although most are suitable for light use, breeding, or as comfortable pasture animals. Those with milder forms of compression and modeling or tapering of the third and central tarsal bones may make competitive athletes.

Fractures of the Distal Phalanx

Nonarticular fractures of the palmar processes of the distal phalanx occur with high frequency in Thoroughbred foals (Figure 128-5). Other types of fractures of the distal phalanx occur but are less common. The forelimbs frequently are involved, and the lateral palmar process is more commonly fractured; bilateral and biaxial fractures occur occasionally. In the hindlimb, medial and lateral plantar process fractures occur evenly. Palmar/plantar process fractures may be detected radiologically as incidental findings and may not necessarily cause lameness.

Salient clinical findings associated with a fracture of a palmar/plantar process of the distal phalanx include acute onset of lameness, which may be intermittent in nature, and lameness that is almost always more noticeable on sharp turns. Foals consistently have pain when hoof testers are applied across the heel. Atypically a response may be noticed with pressure at the toe. When diffuse pain is noted during hoof tester evaluation, along with an

Fig. 128-4 • Slightly oblique lateromedial radiographic image of a hock of a mature horse with crushing of the third tarsal bone and secondary osteoarthritis of the centrodistal and tarsometatarsal joints, the result of incomplete ossification of the third tarsal bone as a neonate. Note the wedge shape of the third tarsal bone and the abnormal dorsal contour.

increased temperature of the foot, subsolar abscessation should be considered.

Treatment includes confinement to a small area with soft, uniform footing for 4 to 6 weeks. Lameness should improve in the first week. External coaptation, such as a foot cast or glue-on shoe, is contraindicated and may potentiate development of club foot conformation. Follow-up

Fig. 128-6 • Dorsolateral-palmaromedial oblique radiographic image of a metacarpophalangeal joint of a foal. There is a wedge-shaped basilar fracture (arrow) of the lateral proximal sesamoid bone.

radiographs are not mandatory unless lameness persists or recurs. The prognosis is good. Differential diagnosis in foals suspect of fracture of the distal phalanx includes subsolar bruising, subsolar abscessation, infectious osteitis of the distal phalanx, and infectious arthritis of the distal interphalangeal (DIP) joint.

Fractures of the Proximal Sesamoid Bones

Fractures of the PSBs are common in young foals. Fractures usually are confined to one limb, but several limbs may be involved. Uniaxial (one) or biaxial (both PSBs) fractures in a single limb can be found. PSB fractures occur most commonly in foals between 2 weeks and 2 months of age. Fractures most often involve the base or apex of the PSB (Figure 128-6). Midbody PSB fractures occur less commonly. Hindlimb PSB fractures are less common, but they generally occur in conjunction with PSB fractures in a forelimb.

Lameness varies from moderate to severe and is exaggerated on turns. Often increased digital pulse amplitude is apparent, and palpation of the involved bone elicits a painful response. Depending on the fracture type and location, the fetlock joint capsule may be distended or regional swelling may occur over the fractured PSB. Diagnosis is confirmed radiologically.

Conservative management is recommended and involves confinement to a small area for 6 to 8 weeks. If swelling is noticed, a distal limb bandage should be applied. Surgical repair is not beneficial in foals because of the lack of substance of the PSBs. Prognosis depends on the type of fracture, number of PSBs involved, and the number of limbs involved. Most PSBs have an elongated appearance (megasesamoid) after fractures heal, but foals may be suitable for athletic use if healing is complete (Figure 128-7). The prognosis for athletic use is worse if both PSBs in one limb are affected, or if fractures occur in more than one limb, compared with a uniaxial fracture in a single limb.

Fig. 128-7 • Dorsolateral-palmaromedial oblique radiographic image of the metacarpophalangeal joint seen in Figure 128-6, obtained when the horse was a yearling. The basilar fracture of the lateral proximal sesamoid bone has healed, resulting in an elongated, distorted appearance of the bone.

Developmental Orthopedic Disease

Developmental orthopedic disease (DOD) is an uncommon cause of lameness in foals less than 2 to 4 months old.^{3,8} However, DOD is a common skeletal disease in weanlings and yearlings and generally is considered self-limiting. DOD is complex and includes acquired flexural deformity, osteochondrosis, physal dysplasia (physitis) and resulting angular limb deformity, and cervical vertebral malformation. The pathogenesis, clinical manifestations, and management are discussed in Chapters 54, 57, 59, and 60.

Diagnosis of osteochondrosis is based on clinical evaluation and radiological findings.^{3,8} Clinical findings include synovial distention and varying degrees of lameness in the acute stage. Most young foals (<2 months old) afflicted with osteochondrosis have several joints or bones involved. These foals are subsequently lamer than older foals and usually have severe osteochondrosis. The cause often is not found because individual foals usually are involved, although heredity likely plays a primary role. Radiological findings may initially include osteochondral fragmentation or erosive changes in subchondral bone, or may be normal. Therefore it is important to plan on serial radiological studies to monitor the progression of changes.

Conservative management for young foals with osteochondrosis almost always is recommended and includes rest, antiinflammatory drugs, systemic chondroprotective drugs, and occasionally joint lavage and injection with hyaluronan. If a free fragment is evident, surgical retrieval may be beneficial; however, one should keep in mind that surgery for osteochondrosis is an elective procedure that should be performed at a time optimal for the foal. If a nondisplaced fragment occurs in a weanling or younger age foal, surgery may be delayed until the yearling period and monitored radiologically (Figure 128-8). Time will allow maturation of the underlying bone so minimal debridement and curettage will be necessary. In many instances the extra time allows these fragments to remineralize, and surgical removal is not necessary. In a longitudinal study of 43 Dutch Warmblood foals, osteochondrosis lesions were found at the cranial aspect of the intermediate ridge of the tibia in 68% at 1 month of age, but at 11 months of age abnormalities were detected in only 18%.⁹

Fig. 128-8 • Lateromedial radiographic image of a stifle. There is irregularity in the outline of the cortex of the lateral trochlear ridge of the femur with subtle alteration of the subchondral bone opacity. This is the result of osteochondrosis. There are no displaced fragments; therefore surgery as a weanling is not required, although the foal should be monitored both clinically and radiologically.

Lesions in the lateral trochlear ridge of the femur developed later, with an incidence of 20% at 5 months of age, but by 11 months of age abnormalities were detected in only 3%.

Vascular Thrombosis

Vascular thrombosis is an unusual cause of lameness in foals. Usually a central focus provides emboli, the most common being a vegetative lesion on a heart valve. Clinical signs include a variable degree of lameness involving one or more limbs. The limb may feel cold during periods of lameness but normal at other times. Response to diagnostic analgesia is inconsistent. Ultrasonographic examination of the heart usually reveals a lesion on a heart valve. Although any valve may be involved, most commonly the aortic or mitral valves are affected. Bacterial blood cultures should be obtained, especially during febrile episodes, if present.

Treatment consists of long-term antimicrobial drugs, based on bacterial cultures if available, and optionally rheological agents such as pentoxifylline. Follow-up ultrasonographic examination is important to determine the effectiveness and duration of treatment. The prognosis is guarded and depends on the degree of ischemia in the distal extremity.

Traumatic Nerve Injury

Collision injuries involving the proximal aspect of the forelimb of foals may result in injury to the radial nerve or components of the brachial plexus. Most commonly a foal has a dropped elbow, is unable to advance the limb, and drags the limb during ambulation. Differential diagnosis includes fracture of the humerus, the scapula, or a cranially located rib, and radiological evaluation should be performed to differentiate these conditions. The condition may be transient, lasting only a few hours if attributable to neuropraxia, or may be permanent.

Treatment for nerve injury consists of antiinflammatory drugs, including corticosteroids and nonsteroidal drugs, and dimethyl sulfoxide. Supportive care, such as

physical manipulation of the limb and splinting, may aid in preventing flexural limb deformity. Acupuncture may be beneficial in some foals with nerve injury. In general, if no improvement is seen within 3 to 5 days of treatment, only 25% of foals recover.

Miscellaneous Soft Tissue Injury

Muscle tears are common in young Thoroughbreds. Longitudinal rents, 3 to 5 cm in length, in the biceps femoris, superficial gluteal muscles, or vastus lateralis are most often seen. Commonly there is a fluctuant fluid pocket in the tear, which resolves over several weeks as the edges of the tear undergo fibrosis. Lameness is usually mild to moderate and transient in nature, lasting for several days. Less common soft tissue injuries include traumatic rupture of the suspensory apparatus or rupture of the gastrocnemius muscle, and foals with these injuries have generally had a poor prognosis for long-term athletic function. However, in a recent report 23 (82%) of 28 foals with rupture of the gastrocnemius muscle survived to discharge from the hospital, and 13 (81%) of 16 horses that reached 2 years of age trained or raced.¹⁰

INFECTIOUS CAUSES OF LAMENESS

Determining the location and cause of lameness in foals attributable to infection is crucial in deciding a course of therapy and assessing prognosis. As a general rule, assuming that all foal lameness is infectious in origin until proved otherwise is safest. In this instance, prompt appropriate treatment uniformly results in a more favorable outcome than if treatment is delayed.¹¹

The clinical complex of infectious arthritis, tenosynovitis, infectious osteitis, or osteomyelitis occurs in foals commonly,¹¹⁻¹⁶ especially in foals less than 4 months of age but occasionally in older foals. The different forms of

infection can be discussed together because the pathogenesis is common. Bacteria may gain entry through the umbilicus, respiratory tract, or gastrointestinal tract, although direct penetration of a synovial structure from external trauma may result in synovial infection. Hematogenous dissemination of bacteria allows localization into metaphyseal, physeal, or epiphyseal cartilage and is believed to be associated with the rich vascular network composed of metaphyseal loops, sinusoidal veins, and epiphyseal and transphyseal vessels that supply the end of the long bones and synovium (Figure 128-9).^{2,13} The sluggish blood flow and vascular stasis of nutrient vessels approaching a cartilage interface allows bacteria to proliferate and colonize. Bacterial colonization incites an acute inflammatory response associated with kinin, complement, and coagulation system activation, eventually leading to cartilage destruction. Vasoactive amines and prostaglandins acting as chemotactic agents result in rapid accumulation of inflammatory cells. Inflammatory products released from synoviocytes, fibroblasts, chondrocytes, neutrophils, and monocytes result in the degradation of articular cartilage proteoglycan, collagen, and hyaluronan. Mediators involved include collagenases, elastases, lysosomal enzymes, plasmin, prostaglandins, metalloproteinases, monokines, and free radicals. Extrinsic mediators include interleukins, bacterial lipopolysaccharides, and physical forces placed on the damaged cartilage, all of which further compound collagen degradation. Further compromise of cartilage occurs because of poor nutrition of the chondrocytes, caused primarily by fibrin clot formation over the articular surface, and by thrombosis in the synovial vasculature. The primary mediators of infectious arthritis and eventual cartilage destruction are toxic metabolites released from chondrocytes. Cartilage matrix degradation and proteoglycan loss may occur within 2 days and collagen loss by 9 days after bacterial inoculation.^{2,17,18}

Fig. 128-9 • Vascular supply to long bone and articular soft tissue. Blood-borne bacteria may colonize at the metaphyseal vascular loop and disseminate to the physis, epiphysis, or synovial membrane. (Modified from Kobluk CN, Ames TR, Geor RJ, editors: *The horse: diseases & clinical management*, Philadelphia, 1995, Saunders.)

Fig. 128-10 • Morphology of the long bone and types of S, E, P, and I infections. *P type*, Physeal-type infectious arthritis; *I type*, bacterial invasion into a physis or joint from a periarticular abscess; *S type*, infectious synovitis; *E type*, epiphyseal-type infectious arthritis. (Modified from Kobluk CN, Ames TR, Geor RJ, editors: *The horse: diseases & clinical management*, Philadelphia, 1995, Saunders.)

No explanation is apparent for disease localization in the epiphysis, metaphysis, physis, or joint. However, certain joints do appear to be affected more frequently than others. For example, the stifle, hock, metacarpophalangeal, and metatarsophalangeal joints are involved more often than the carpus or pastern. Infectious arthritis and osteomyelitis of hematogenous origin have been classified into five types based on location of the structure involved (Figure 128-10).^{13,19}

Infectious synovitis (*S type*) affects foals usually within the first 10 days of life. Several joints are usually involved, and few, if any, radiological changes are seen. Predominant clinical signs include periarticular soft tissue swelling, effusion, and lameness. Arthrocentesis reveals an elevation in nucleated cell count (usually >50,000/mcL), and degenerate neutrophils predominate.

Epiphyseal-type (*E type*) infectious arthritis involves the joint and adjacent epiphysis. Foals are generally several weeks of age or older. One or more joints may be infected, and other systemic illnesses may occur concomitantly. Radiological evidence of epiphyseal involvement commonly is seen.

Physeal type (*P type*) may occur in foals from 1 week to 4 months of age. Degree of soft tissue swelling and lameness may vary, and generally only one site is involved. Sympathetic effusion eventually may occur in a nearby joint (articular structure in close proximity). Lesions may be seen radiologically in the metaphysis, physis, or epiphysis (Figure 128-11). Pathological fracture may result because of weakening of the involved structure.

Small tarsal or carpal cuboidal bone (*T type*) osteomyelitis may result in collapse of the central or third tarsal bones (Figure 128-12). Several joints commonly are affected.

Fig. 128-11 • Dorsopalmar radiographic image of a carpus of a foal with *P-type* osteomyelitis of the distal radial physis. Lateral is to the right. Note the soft tissue swelling and the extensive radiolucent areas in the physis, metaphysis, and epiphysis. Infection has caused fragmentation of the lateral aspect of the metaphysis.

Fig. 128-12 • Dorsoplantar radiographic image of a hock of a young foal with type T osteomyelitis involving the cuboidal bones of the tarsus. Lateral is to the right. Note the mottled opacity of the central and third tarsal bones and the proximolateral aspect of the third and fourth metatarsal bones. These extensive lesions warrant a grave prognosis.

Invasion into a physis or joint from a periarticular soft tissue abscess is called I-type infection. Most commonly joints of the upper part of the limb, such as the hip or stifle, are involved. If soft tissue abscessation is detected early, infectious arthritis often can be avoided.

Most commonly foals with osteomyelitis have acute-onset lameness, diffuse regional swelling, heat, and detectable pain of the involved area. Fever is generally present before and at the onset of lameness but may go undetected. Degree of lameness depends on what bone is involved, the time frame, and stage of detection. Owners often erroneously assume lameness results from trauma because signs occur acutely. A common assumption is that the mare stepped on the foal (the Editors).

Diagnosis of complex infection is based on physical examination findings and the results of arthrocentesis (if intrasynovial involvement occurs) and radiographic examination.^{2,11,13,15,16} Foals with infectious osteitis or early osteomyelitis may have no or subtle radiological changes, but within 1 to 2 weeks radiological changes consist of erosive, radiolucent changes surrounded by increased radiopacity and eventual proliferation of new bone. Therefore it is important to perform follow-up radiology to monitor the progression of the disease.

Other imaging modalities are of limited value. Sensitivity of nuclear scintigraphy alone is questionable in young foals because of the high metabolic activity of developing bone.¹⁰ Labeled white cell imaging using nuclear medicine techniques is useful but adds expense and radiation exposure and has not gained widespread acceptance in private practice.

Ultrasonographic examination is most helpful in identifying soft tissue injury or inflammatory processes in the upper limb. Abscessation of the soft tissue adjacent to the infected bone is a common finding in foals with physeal infection. Using ultrasonographic guidance, abscesses can be aspirated for culture and antimicrobial susceptibility testing and opened, drained, and lavaged.

Arthrocentesis is the key in diagnosing infectious arthritis, but a negative culture does not rule out infection.^{4,11-15,20} Joint fluid should be obtained in ethylenediaminetetraacetic acid tubes to evaluate the differential and total nucleated white blood cell count and protein concentration and for cytological evaluation. Anaerobic and aerobic culture and antimicrobial susceptibility tests should be performed. Using an antimicrobial-removal device may be of benefit to potentiate a positive culture if the foal is receiving antimicrobial drugs. Blood cultures should be collected.

In foals and horses suspected of having infectious arthritis, synovial fluid cultures are positive 64% of the time.^{12,14,17,18,20} In my practice, of 158 synovial samples submitted in 1 year, there were only 64 (40%) positive isolates. Reasons for low positive culture results include previous administration of antimicrobial agents, partial success of the immune system, the intrinsic bacteriocidal properties of infected synovial fluid, poor storage, or no bacteria present in the synovial fluid.

If there is radiological evidence of osteomyelitis well away from a joint, a sample of bone and debris may be obtained using a Michelle trephine. An alternative technique is to use a 2.5- or 3.2-mm drill bit and collect the shavings for culture and antimicrobial susceptibility testing.¹¹ This tract then may be used for intraosseous infusion of an antimicrobial agent.

The results of hematological testing can be confusing. Complete blood count and fibrinogen level should be assessed, but results are often within normal limits initially because infection is localized. Serial hemograms should be performed in this instance. Any elevation in the white blood cell count or fibrinogen level in a lame foal with fever should be assumed to reflect bone or joint infection until proved otherwise. A normal hemogram does not rule out infectious arthritis or osteomyelitis. Foals less than 1 month of age should have immunoglobulin G levels checked to evaluate for failure of passive transfer.

Treatment of foals with infectious arthritis consists of joint lavage with sterile polyionic fluids through large-bore needles or by using an arthroscope. If a large amount of fibrin and cellular debris is in the synovial fluid, arthrotomy and lavage with or without primary closure of the joint may be indicated. Joint lavage may be repeated every 1 to 3 days depending on the clinical response. A long-term closed suction drainage system may be used as well.¹¹ Broad-spectrum systemic antimicrobial drugs should be started immediately and adjusted accordingly based on the clinical progression and culture and antimicrobial susceptibility testing.

Other treatments for joint and bone infection include local intraosseous injection or regional hyperperfusion with antimicrobial agents. To perform intraosseous injection, an 18- or 20-gauge needle is inserted into the physis or adjacent bone. An aminoglycoside such as amikacin (250 to 500 mg) may be used. Alternatively, a cannulated

Fig. 128-13 • A, Sussmane-Raszynski intraosseous infusion needle (Cook Incorporated, Bloomington, Indiana, United States). **B,** Dorsopalmar radiographic image showing an intraosseous infusion needle inserted in the distal radius of a weanling to manage P-type osteomyelitis of the distal medial radial physis.

intraosseous infusion needle (Sussmane-Raszynski intraosseous infusion needle, Cook Incorporated, Bloomington, Indiana, United States) may be inserted and maintained for repeat use (Figure 128-13). To perform regional hyperperfusion, a site over the lateral digital neurovascular bundle is prepared aseptically, and a rubber Esmarch tourniquet is placed in the proximal metacarpal region. A 23-gauge butterfly catheter is inserted in the digital vein. An antimicrobial solution (500 mg of amikacin diluted in 10 mL of sterile water) is infused into the digital vein. The tourniquet is removed after 15 minutes, and a lower-limb bandage is applied. The procedure may be repeated as necessary. Regional digital hyperperfusion is especially useful in treating foals with infectious osteitis of the distal phalanx and infectious arthritis or osteomyelitis of the distal aspect of a limb. I have not encountered complications, such as distal limb ischemia, from tourniquet application.

Foals with infectious arthritis should be allowed to rest for a minimum of 3 to 4 weeks to prevent further traumatic cartilage damage.² Systemic administration of

chondroprotective agents or intraarticular administration of hyaluronan may be of benefit.

Severe erosive lesions of the physis and metaphysis may result in pathological fracture and collapse of the bony column, resulting in an unstable fracture or severe angular deviation. Surgery may be indicated, but prognosis is poor for soundness if this occurs.

The prognosis for foals with infectious arthritis and osteomyelitis depends on the antimicrobial susceptibility of the organism and how early effective treatment is instituted.¹²⁻²⁰ In general, foals treated early for articular infections have a good prognosis for full recovery. Foals with articular infection with subchondral bone involvement have a poor prognosis, and the clinical course of disease and treatment are prolonged. Foals with focal bony lesions, involving only the physis without bone instability, have a good prognosis. Those with a pathological fracture or severe angular limb deformities have a poor prognosis and may be candidates for humane destruction.

Immune-Mediated Synovitis

Immune-mediated synovitis is a sequela to a primary inflammatory focus such as pneumonia, umbilical remnant infection, or a peripheral abscess.^{11,21} *Rhodococcus equi* pneumonia is the most common primary focus of infection. The syndrome results from the deposition of immune complexes in the synovial lining and complement activation, resulting in synovitis. The condition usually involves more than one synovial structure. Foals usually have a stiff gait resulting from the synovial distention, and severe lameness is unusual.

The primary rule out for immune-mediated synovitis is early infectious polyarthritis, causing only moderate lameness and mild synovial fluid distention. Cytological evaluation of joint fluid in foals with immune-mediated synovitis commonly reveals nucleated cell counts of less than 20,000 nucleated cells/mcL. The cells are well-preserved neutrophils and large mononuclear cells. Foals with infectious arthritis generally have nucleated cell counts greater than 50,000 nucleated cells/mcL, and neutrophils are degenerate.

Therapy for foals with immune-mediated synovitis is based on identifying and resolving the underlying disease. Synovitis is self-limiting once the offending cause is removed. Systemic chondroprotective agents may be of benefit to the health of the joint because prolonged inflammation may cause cartilage damage.

Infection of the Digit

Infection of the digit is a frequent cause of severe lameness in foals. Infection may be contained to the subsolar or hoof wall regions, or it may involve the distal phalanx or the DIP joint. It is critical to differentiate between these sites as soon as possible. Infection at all sites causes increased intensity of the digital pulse amplitudes and, at some stage, increased temperature of the hoof capsule. With subsolar or wall abscessation, pressure applied with hoof testers usually produces a painful response along the toe and sole, unless overlying horn is separated from the sensitive tissue caused by accumulation of purulent material. Radiology in these foals reveals gas accumulation in the involved area. If the distal phalanx is infected, radiolucency or sequestration may be evident. Diffuse swelling at the coronary band

usually means involvement of the DIP joint, and arthrocentesis should be performed in an area remote from the swelling.

Subsolar abscesses should be drained early to prevent involvement of deeper tissues. To facilitate drainage, the foot can be soaked in hot water and bandaged with an Animalintex pack (3M Animal Care Products, St. Paul, Minnesota, United States). Both procedures soften the horn. Surgical curettage of the distal phalanx and lavage of the infected bone should be performed in foals with sequestration. A sterile, antiseptic bandage should be maintained

after surgery for a minimum of 3 to 4 weeks or until a healthy keratin covering has grown over the exposed bone. Ancillary treatment includes regional digital hyperinfusion using a dilute antimicrobial solution. A good prognosis is warranted in foals with infection of the distal phalanx if the disease is detected and treated early. If more than 25% of the distal phalanx is involved, prognosis for future soundness worsens. Recurrence of infection after initial curettage requires additional surgery. Because of the limited surface area and porous nature of the distal phalanx in the foal, recurrence worsens the prognosis considerably.

Chapter 129

Pleasure Riding Horse

Herbert J. Burns

Pleasure riding horses are a vital part of the equine industry, and many owners devote great amounts of time, money, and emotion to them. Although pleasure riding horses are of far less monetary value than competition horses, the overall importance to the owner should never be underestimated.

Pleasure riding horses often tend to be used seasonally and somewhat episodically. Uses include trail riding, hunting, gymkhana-type activities, showing, lesson horses (teaching horses), the pasture pet, and eating grass. Pleasure riding horses can be divided loosely into two categories: former professionals and others. The *former professionals* are horses that formerly were used for a specific athletic use, such as racing, but are no longer able to perform in the sport and have been demoted. The *others* include potential athletes that were unable to be used for the intended purpose because of lack of ability, poor conformation, or temperament, as well as horses and ponies that were bred casually as pets. The common causes of lameness in these two groups differ to some extent.

It is vital to be able to relate to the owners of pleasure riding horses, who often are inexperienced with horses, have little veterinary knowledge, but have tremendous emotional involvement with the horse and are often anxious. It is critical to first establish communication with the owner and try to relieve any anxieties. The veterinarian should explain the intended examination and treatment in straightforward, nontechnical language. Facilities for examination may be far from ideal and may complicate the examination. The veterinarian should not overinterpret a short striding gait shown by a horse trotting on an uneven paddock or a rocky driveway. The clinician should start from the basics and evaluate left-right symmetry, with the horse standing on a flat, level surface, if available, and then assess the horse moving in straight lines and circles. The veterinarian should be aware that the horse may have been living with a low-grade lameness, unrecognized by the owner, for a considerable time. If the owner

is concerned about severe left forelimb lameness, the veterinarian would be prudent to avoid mentioning low-grade left hindlimb lameness observed concurrently because the lameness is probably not of material relevance and will only further worry the owner.

Interpretation of findings is in part dictated by the age and previous occupation of the horse. Many former professional horses have previous soft tissue injuries or show lameness after flexion of a variety of joints, and it is important to try to establish which is the current active disease process causing lameness. Many clinical observations reflect previous injuries and are unrelated to the current lameness.

Local analgesic techniques are useful in some situations, but the temperament of the horse, difficulties in adequate restraint, or examination facilities available may mitigate against them. Owners of pleasure riding horses may resist techniques that are invasive or potentially painful to the horse, whereas they may be fully prepared to pay large sums for advanced diagnostic techniques. The clinician should bear in mind that a twitch in the inexperienced hands of an owner may be dangerous and should consider using tranquilization (e.g., 20 mg of acepromazine) in the horse to facilitate local analgesic techniques.

In some situations an owner prefers a step-by-step diagnosis reached by assessing the response to treatment, even without a definitive diagnosis. This can provide the slow acquisition of useful information. For example, assessment of the response to nonsteroidal antiinflammatory drug treatment can be helpful. Lameness associated with a subsolar abscess is likely to deteriorate, whereas lameness from navicular disease or osteoarthritis (OA) of the proximal interphalangeal joint is likely to improve.

In former professional horses, OA and previous tendon and ligament injuries are common. Minor trauma to a joint in a horse with preexisting OA may result in severe, persistent lameness, whereas similar trauma to a normal joint probably would not result in chronic lameness. Commonly injured joints include the carpus, fetlock, hock, and stifle. Superficial digital flexor tendonitis, suspensory desmitis, and distal sesamoidean ligament injuries are common chronic injuries in former professional horses, but reinjury is comparatively unusual unless the horse is subjected to a sudden and substantial increase in exercise intensity; for example, a horse is ridden hard for 2 hours after 3 months of little or no exercise. Previous sites of chronic

inflammation may become a long-term problem. For example, a horse may lose a shoe and then gallop about on hard ground, resulting in solar bruising. However, lameness may persist, and radiographs may reveal osteitis of the palmar processes of the distal phalanx. A horse with toed-out conformation may traumatize the medial proximal sesamoid bone, resulting in acute lameness, but radiology may only reveal preexisting abnormalities.

Many causes of lameness in pleasure riding horses relate to the lifestyle of pampered pets and the environment in which they are kept. Subsolar abscesses are common and often result in a severe lameness, creating panic for an owner, who assumes the horse must have sustained a fracture. Managing the owner is equally as important as treating the horse. Subsolar abscesses also may be sequelae to previous laminitis.

Creation of effective drainage is essential for successful management of subsolar abscesses. Without drainage, the use of systemic antimicrobial drugs is contraindicated in my experience because such drugs may prolong the course of the infection. In some pleasure riding horses with a hard hoof capsule, determining accurately the site of abscess may not be possible initially. I recommend intensive soaking with Epsom salts and warm water and poultice at night. Periodic survey radiographs can be useful. In horses with long-standing abscessation the appearance of a radiolucent defect associated with gas accumulation deep to the hoof capsule may allow direct drainage of the abscess through the hoof wall, rather than through the sole (Figure 129-1). Up to 30 days may pass before the abscess can be located accurately and drainage can be established. Once the abscess has opened or been opened, systemic antimicrobial drugs may be useful, especially if a large area of the foot is damaged.

Pleasure riding horses are at high risk for sustaining lacerations or puncture wounds, often resulting from impact with less than ideal fencing, such as barbed wire or a jagged post. Injuries vary from minor to severe, resulting in long-term lameness. Injuries may go unrecognized for several days because not all pleasure riding horses are inspected carefully and regularly. Many pleasure riding horses are kept in groups at pasture, and the introduction of a new horse can result in disruption of the hierarchy and the risk of horse-induced injury.

The veterinarian also should recognize that many pleasure riding horses have major conformational abnormalities

Fig. 129-1 • Lateromedial radiographic image of a foot in a pleasure riding horse with a long-standing subsolar abscess. Once a radiolucent defect is identified, a small hole can be drilled and the abscess cavity drained and medicated without opening the abscess from the sole. Lameness in this horse resolved soon after the abscess was drained.

that predispose them to the early development of OA. Many pleasure riding horses live to an old age, and age-related OA is not uncommon. Farrier care may be less than ideal and may predispose the horses to chronic foot pain and OA of the distal limb joints. Nail bind and excessive shortening of the toe are common farriery-related causes of lameness. It is important to establish the time of onset of lameness relative to when the horse was last shod. These problems are usually apparent within 48 hours. If a nail was driven inside the white line and immediately removed, this may predispose the horse to a subsolar abscess, which usually causes lameness within 7 to 10 days. If foot lameness develops more than 2 weeks after trimming and shoeing, the lameness is unlikely to be related to the farrier. Other primary foot problems include solar bruising, sheared heel, puncture injuries, and thrush. The relative incidence of these problems may be related to the ground conditions if the horse lives outside. Early, wet springs increase the incidence of thrush. Long, dry summers resulting in hard ground are associated with an increased incidence of bruising and sore feet.

Laminitis is a problem seen most commonly in two types of pleasure riding horses: obese ponies and older horses and ponies with a pituitary adenoma (pituitary pars intermedia dysfunction, equine Cushing's disease). Laminitis is often seasonal, occurring most in the spring and early summer and also in the autumn, if a flush of grass occurs late. Navicular disease is not uncommon, and an irregular exercise history may be a predisposing factor. Navicular disease is less common in horses that have never been shod.

Cellulitis can create an acute-onset, non-weight-bearing lameness associated with pyrexia and inappetence. In some horses minor skin abrasions can be identified through which infection was initiated, but in others the primary cause may not be identified.

The incidence of tendon and ligament injuries is low and may be related to the weather and environmental conditions or to the age of the horse. Excessively deep, muddy pastures and extremely icy conditions may predispose horses to tendonitis or desmitis. Age-related degenerative changes take place in some tendons and ligaments, and in older pleasure riding horses, even those receiving no ridden exercise, sudden onset of a severe, progressive tendonitis of the forelimb superficial digital flexor tendons may develop. Progressive stretching of the hindlimb suspensory apparatus, resulting in dropping of the fetlocks, also occurs in older horses.

Neurological problems such as radial nerve paralysis may result from trauma induced by a kick from another horse in the same field or from a collision with another horse or a static object such as a gate post. In older horses, neoplastic lesions may result in secondary lameness. For example, a large melanoma in the gluteal region of a horse I examined created pressure on the sciatic nerve and thus lameness.

Pleasure riding horses are often kept at pasture in a group, with access to field shelters of variable design. Long bone fractures, the result of a kick from a companion horse, are not uncommon, especially during the winter months. Splint bone fractures are also common.

Treatment of many of these conditions is no different than in other athletic sports horses; however, certain

constraints may apply that must be considered. No facilities may be available to restrict the horse's exercise or to keep it on its own. Even if surgery is contemplated, box stall rest—mandatory after most procedures—may not be possible because there may not be a stall. Some facilities are completely inadequate for performing clean procedures, such as intraarticular medication, in a safe manner. However, owners often are prepared to spend a disproportionate amount of their income on treating a condition in their much loved horse, despite a guarded prognosis; therefore it is important to describe all available treatment options. It is also critically important to explain carefully the treatment protocol, and writing it down can be useful to ensure owner compliance. The veterinarian can create a chart that the owner should complete as medication is administered.

In managing OA, the fact that a pleasure riding horse lives outside and is constantly exercising may be of benefit. I prefer to start with the least invasive therapy first and only use alternative methods if that does not work. Some oral nutraceutical agents may be of benefit, as may be intramuscular administration of polysulfated glycosaminoglycans.

Management of wounds can be difficult because client compliance is often poor. I treat pleasure horses with wounds in anticipation of a worst-case scenario, using non-steroidal antiinflammatory drugs, broad-spectrum antimicrobial drugs, and confinement. Complete stall rest is often impossible, and restricted area turnout is a frequent compromise. If a penetrating injury possibly may have entered a joint or tendon sheath, I recommend referral for intensive therapy, stressing to the owner that this injury is potentially life threatening.

Color Plate 1 • Normal dorsal, palmar, left lateral, and solar thermographic images of the distal aspect of the forelimbs of a horse. There is good symmetry between the limbs. The coronary band is the warmest area, and the rest of the hoof becomes colder in a regular pattern closer to the ground surface. The palmar image shows a normal increase in temperature between the heel bulbs. On the solar image there is a V-shaped pattern of increased temperature representing the sulci of the frog.

Color Plate 2 • An advanced event horse with previous history of midbody superficial digital flexor tendonitis of the right forelimb. More recently peritendinous edema had developed distally in the right forelimb. Ultrasonographic images show increased cross-sectional area of the superficial digital flexor tendon, and areas of hyperechogenicity and hypoechogenicity. It was not possible to determine if there was active pathology or if this was the level of healing that had been reached from the previous injury. The palmar thermographic image shows rectangular clip artifacts on both limbs. There is a clinically significant increase in temperature of the distal palmar aspect of the right forelimb compared with the left, indicating inflammation, and thus the image suggests recurrent tendon injury.

Color Plate 3 • Three examples of muscle injury. The left thermographic image shows a left gluteal injury with increased heat signature. The middle image shows an increase in temperature over the biceps femoris muscle. The right image is of a chronic gluteal injury with fibrosis, which has a cooler thermal pattern.

Color Plate 4 • The left and middle thermographic images are caudodorsal views of the back, showing areas of increased temperature associated with clinical signs of back pain and impinging dorsal spinous processes evident radiologically. The lateral view of the neck is from a horse with marked caudal cervical facet joint osteoarthritis. There is an increase in superficial blood flow in this region.

Color Plate 5 • Thermographs show the appearance of normal horses. The color scale represents 5.6° C, using 10 colors; that is, each color represents about a 0.5° C change in temperature. The color bar under the image shows the colors used; those to the right side are the hottest, and those to the left are the coldest. White is above the top of the scale, and black below the scale. **A**, Lateral image of the head, neck, and shoulder. **B**, Lateral image of the thorax, abdomen, and hindquarters. **C**, Oblique dorsal image from behind the horse looking toward its head and neck. Temperature variation is 1° C over the neck, trunk, and hindquarters. A warm midline dorsal stripe along the back extends from the withers to the base of the tail, with symmetrical muscle temperature on either side.

Color Plate 6 • Lateral image of the neck of a horse with reduced mobility in the occipitoatlantal and atlantoaxial joints. A cool line (red) runs obliquely from the region of the atlantoaxial joint caudally to the base of the neck and is 1.5° C cooler than the surrounding muscle, indicating an area of sympathetic dystonia.

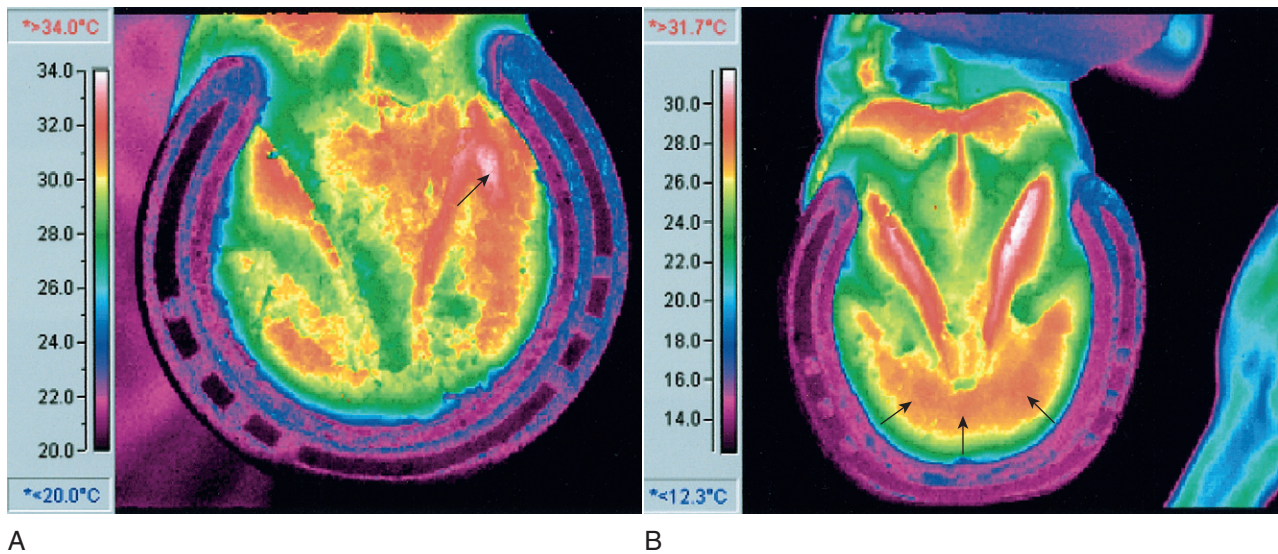

Color Plate 7 • Lateral image of the neck of horse with reduced mobility in the neck. Note the cooling (red area) from the occiput back to the level of the sixth and seventh cervical vertebrae, indicating a problem involving all joints in the neck.

Color Plate 8 • Lateral images of the thoracolumbar area of two horses, both showing clinically significant cooling (red area) in the musculature of the dorsal spine from the saddle region caudally. **A**, The vertical cranial boundary to the zone of cooling indicates that the injured area is in the region of the cervicothoracic junction, but the shoulder muscles overlying this area receive innervation from the lower neck, partly masking the muscles supplied by the upper thoracic area. **B**, The typical appearance of cooling in the muscle resulting from an injury to the region of the twelfth thoracic vertebra, with the cranial border of the region running obliquely down and back. This horse has been clipped, but long hair left on the hindlimb shows as an area 5° C cooler than the surface temperature of the thorax of the horse.

Color Plate 9 • Dorsal image of a horse with abnormal temperature patterns of the thoracolumbar spine. Note the complete loss of the normal central stripe (compare with Color Plate 5, C), with cooling indicating the presence of reduced mobility of the entire thoracolumbar spine and pelvis. The asymmetrical nature of the temperature pattern indicates the horse is likely to move with an asymmetrical gait, resulting from increased muscle tone on the left side of the body.

Color Plate 10 • Examples of different thermographic foot patterns (solar images). **A**, This hoof has a medial corn (*arrow*), manifested as a focal hot spot (*white*) within an area of increased temperature. **B**, This hoof has subacute laminitis, with a pattern of increased temperature in the region of the tip of the distal phalanx (*arrows*).

Color Plate 11 • Palmar thermographic image and subsequent transverse (*left*) and longitudinal ultrasonographic images (see Figure 117-5) of an advanced event horse 10 days after successfully completing a Three Day Event. The horse was having a routine examination, and no clinical localizing signs were evident in the tendon. The thermogram demonstrates a focal hot spot over the left distal superficial digital flexor tendon (*arrow*), and the ultrasonographic images reveal a hypoechoic core lesion in the same region.

Color Plate 12 • Computerized saddle pressure analysis images. Cranial is to the left, and left is to the bottom. **A**, This image shows a poorly fitting saddle, with a focal pressure point in the left withers region (*arrow*). **B**, This image demonstrates failure of a gel pad to alleviate the pressure point and the development of an additional pressure point caudally (*arrow*).

Normal Gait

1. Gait of a normal horse when evaluated in-hand and while lunged
2. Gait of a normal horse while ridden

Unilateral Forelimb Lameness

3. Left forelimb lameness
4. Right forelimb lameness
5. Unilateral forelimb lameness resulting from upper limb pain
6. Unilateral forelimb lameness resulting from upper limb pain

Bilateral Forelimb Lameness

7. Bilateral forelimb lameness worse in the right forelimb

Effect of Circling on Forelimb Lameness

8. Right forelimb lameness
9. Bilateral forelimb lameness
10. Characteristics of carpal region pain

Hindlimb Lameness without a Head and Neck Nod

11. Left hindlimb lameness in a horse with stifle pain
12. Left hindlimb lameness in a horse with bilateral suspensory desmitis
13. Right hindlimb lameness in a horse with peritarsal soft-tissue injury
14. Right hindlimb lameness
15. Left hindlimb lameness, effect of the pace and trot during lameness examination

Hindlimb Lameness with an Associated Head and Neck Nod

16. Severe right hindlimb lameness from pain associated with fracture of the central tarsal bone
17. Severe left hindlimb lameness
18. Right hindlimb lameness as a result of severe osteoarthritis of the medial femorotibial joint
19. Severe left hindlimb lameness

Bilateral Hindlimb Lameness

20. Bilateral hindlimb lameness and plaiting while trotting
21. Bilateral hindlimb lameness exhibited as a reluctance to work

Effect of Circling on Hindlimb Lameness

22. Right hindlimb lameness and toe drag
23. Toe dragging while circling
24. Right hindlimb lameness worse going to the right

Concurrent Forelimb and Hindlimb Lameness

25. Left forelimb and left hindlimb lameness
26. Left forelimb and left hindlimb lameness in a Standardbred racehorse
27. Left hindlimb and right forelimb lameness causing a "rocking-type" gait
28. Left hindlimb and right forelimb lameness in a trotter before and after low plantar diagnostic analgesia
29. Bilateral hindlimb and mild forelimb lameness in a Thoroughbred racehorse with mal- or nonadaptive subchondral bone remodeling

Other Aspects of Hindlimb Lameness

30. Hindlimb lameness while ridden
31. Gait restriction from thoracolumbar pain
32. Gait restriction from sacroiliac region pain

Neurological Gait Deficits

33. Gait deficit in a horse with a cervical spinal cord lesion
34. Hindlimb ataxia and right shoulder instability
35. Hindlimb weakness
36. Gait deficit in a horse with cervical stenotic myelopathy

Mechanical Gait Deficits

37. Fibrotic myopathy
38. Stringhalt
39. Shivers
40. Upward fixation of the patella
41. Fibularis (peroneus) tertius injury in a mature horse
42. Fibularis tertius avulsion injury in a foal

Esoteric Gait Abnormalities

43. Right hindlimb gait abnormality
44. Running type of hindlimb gait
45. Aortoiliac thrombosis
46. Left hindlimb lameness and gait deficit in a horse with gastrocnemius origin injury
47. Idiopathic shortening of the cranial phase of the stride in a right hindlimb
